THE ENCYCLOPEDIA AMERICANA

Publicola, püb-lik'ō-la, **Publius Valerius**, Roman consul and general; d. between 503 and 496 B.C. He is stated to have been a descendant of a noble Roman family and was present when Lucretia stabbed herself. He was instrumental in the expulsion of the Tarquins, and when Collatinus was forced to resign Valerius was elected consul in his stead in conjunction with Junius Brutus. When the Tarquins, aided by the Veientes, moved against Rome in 509 B.C. they were met by the Romans under the two consuls and defeated. Brutus fell in the battle leaving Valerius sole consul. On the return of Valerius to Rome he began the erection of a home on the Velian hill, but perceiving that the people suspected him of a desire to raise himself to royal power he had the building destroyed and his lictors were ordered to lower their fasces when they appeared before the people. He promulgated a law by which any person who attempted to usurp kingly power might be killed by any one, and another establishing the right of a plebeian condemned by a magistrate to appeal to the people. In recognition of his services he received the surname Publicola, 'the people's friend.' He was three times re-elected consul, conducted the expedition of Porsena, and with his colleague Titus Lucretius Tricipitinus defeated the Sabines in 504. His death is placed by some in the following year, but Niebuhr thinks that he died in the battle at Lake Regillus in 498 or 496. Consult: Niebuhr, 'History of Rome,' Vol. I.; Cicero, 'De Republica.'

Publishing. See AMERICAN PUBLISHING; Book.

Puck, in mediæval mythology, a celebrated fairy, whose character and attributes are depicted in Shakespeare's 'Midsummer Night's Dream.' This fairy is known by a variety of names, as Robin Goodfellow and Friar Rush in England, and in Germany as Knecht Ruprecht; but it is by his designation of Puck that he is most generally known in England, Germany, and the more northern nations. He was the chief of the domestic tribe of fairies, or "brownies," as they are called in Scotland; and innumerable stories are told of his nocturnal exploits.

Pud. See POOD.

Pudding-berries, the berries of the Canadian dogwood (*Cornus canadensis*), common throughout North America. See DOGWOOD.

Puadlingstone. See CONGLOMERATE.

Puebla, La, lä pwäb'lä, Mexico, a State of the Republic and its capital city. The State of La Puebla in the central plateau of the Anahuac has Vera Cruz to the north and west of it, Oaxaca to the south, Guerrero to the southwest, and Morelos, Mexico, Tlaxcala, and Hidalgo to the west. See MEXICO — STATE OF.

Puebla, Mexico, (originally called Puebla de los Angeles), capital of the State of the same name; 116 miles east of the City of Mexico by the Mexican railway, but considerably less than 100 miles in a straight line; altitude over 7,000 feet above the sea. The climate is most agreeable, the maximum temperature being 84° in summer and 75° in winter. The peaks Popocatepetl and Ixtaccihuatl are only about 25 miles distant, and those of Orizaba and Malinche are in plain view. Three steam railways,—the Mexican, the Mexican Southern and the Inter-oceanic, and a street railway which will soon be electrified, supply transportation. Straw hats, leather goods and numerous other articles are manufactured in considerable quantities, and in the immediate vicinity are several large cotton mills. Near by are the famous onyx quarries which have for many years supplied great quantities of beautiful onyx to Mexico and the United States. A manufactory in the city makes of the product of these quarries an endless variety of useful or ornamental objects, from store and saloon fixtures, table tops and wash basins to imitations of every fruit known in the country. The banking facilities of the city are supplied by the Oriental Bank, with \$6,000,000 capital, and branches of the National Bank and Bank of London & Mexico, of Mexico City. The city is noted for its many churches, clean streets, substantial business edifices and grand Cathedral, which was almost 150 years in building, is 323 feet long, 101 feet wide and 80 feet from floor to roof.

The educational institutions besides the Primary and High Schools, are the State College, School of Medicine, Normal School for Men, Norma School for Women, Normal School of Arts, Academy for Belles Arts, and Hospicio for the education of children. There are three public libraries with a total of 78,000 volumes, a museum of archaeology, an art gallery, an observatory, a market hall, sulphur baths, a general hospital founded in 1658, and a maternity hospital, state hospital for both sexes, hospital for the insane, children's hospital, military hospital, Inter-oceanic Railway Hospital and Spanish Beneficiary Hospital. The Palace of the state government, which was recently greatly extended and improved and which faces the principal park or zocolo is one of the notable buildings of the city. The extensive and very beautiful Alameda is a most attractive spot, and contains a monument erected in 1808 in honor of Mexico's liberators, and the monument to General Nicolas Bravo. There are also the French-Mexican monument erected by the French colony in 1902, and the equestrienne statue of General Zaragoza, which surmounts a fine monument erected at the foot of the hill of Guadalupe. In the Government Palace is a most interesting collection of historic paintings and a library of 28,000 volumes. The zocolo or central park of the city is artistically laid out in vine and foliage covered walks, with fountains and statues here and there, and numerous small plazas supply needed breathing spots. There are two theatres. Since 1532, in which year the royal sanction was given to form a settlement here, Puebla has occupied second place among all the cities of the land, commercially, spiritually and in population, until very recently, when Guadalajara forged ahead in population and material development generally.

The city of Puebla was founded in 1532 by the Franciscans, and is considered the military key to the capital of the republic. It was captured by the French in 1863 and recovered by the Republican forces under General (now President) Diaz, in 1867. Tradition asserts that when Cortez came he found a city of 300,000 inhabitants, 400 temples and a legion of priests, six miles distant from Puebla, where now is the famous Pyramid of Cholula; and that the Aztecs came there in great numbers to worship and offer up human sacrifices. Pop. (1906) about 100,000.

Pueblo, pwēb'lo, Colo., city, county-seat of Pueblo County; on both sides of the Arkansas River, at the mouth of Fountain Creek, and on the Atchison, T. & S. F., the Colorado & S., the Denver & R. G., the Missouri Pacific, and the Chicago, R. I. & P. R. R.'s; about 122 miles south by east of Denver. Within its corporate limits are several villages: North Pueblo, Central Pueblo, South Pueblo, and Bessemer. It is in a basin on the eastern foot-hills of the Rocky Mountains. A temporary Mormon settlement was located here in 1846, and a trading post was established in 1850. In 1854 the Ute Indians massacred the residents of the post. In 1859 the present city was laid out, and in 1873 it was chartered as a city. The region of country east is largely devoted to agriculture and stock raising. In the vicinity of the city

are extensive coal and oil fields, and deposits of limestone and iron ore. The silver and copper ores are brought a considerable distance to the smelters of Pueblo; and lead, gold, and zinc are here prepared for the metals of commerce. The iron and steel industries have become quite extensive. The Colorado Fuel and Iron Company (steel plant) have (1904) 6,300 employees; the railroad car-shops and yards, 2,500 employees; the smelters, 3,200; the foundries and other manufactories, 6,000. In 1903 there was invested in manufacturing industries, a capital of about \$13,000,000, and the products were about \$32,000,000, of which amount nearly two thirds was the product of the lead smelting and refining.

The principal public institutions are the State Insane Asylum, Saint Mary's Hospital and Sanatorium (1,000 patients annually), Minnieque Hospital (cost \$300,000), and small private sanatoriums. There are two systems of public schools, one on each side of the river; two high schools, public and parish schools (14,000 school children), Loretto Academy, the McClellan public library with 14,000 volumes, law libraries, school libraries, and the State Mineral Palace and Park. A complete collection of the minerals of Colorado are in the Mineral Palace. The five banks have a combined capital of \$800,000 and deposits of \$10,000,000. The government is administered under a charter of 1887 which provides for a mayor who holds office two years, and a council of eight members. The council confirms the mayor's appointments and elects the police judge, city physician, and the members of the fire department. The treasurer, clerk, engineer, and auditor are elected by the people. The city owns and operates one system of waterworks, and another is owned by a private corporation. The large majority of the population are native-born Americans; about 2,000 are Italians; 1,000 are Austrians, and 1,500 are colored. Pop. (1890) 24,558; (1900) 28,157. The school census of 1903 gives a population of 63,000.

E. W. POERRE,

Secretary Business Men's Association.

Pueblo Indians (Spanish, "town," "village"; hence Pueblos, "villagers"), a group of sedentary agricultural tribes comprising the Tanoan, Keresan or Queres, and Zuñian linguistic stocks in New Mexico, and the Hopi or Moqui of the Shoshonean stock in northeastern Arizona. There are also some Mexicanized remnants of the Tanoan stock on the Rio Grande below El Paso, in Texas, and Chihuahua. For details see under the above stock names.

Physical Characters.—Disregarding those who have been more or less affected by Spanish contact, the Pueblo Indians are generally small in stature, particularly the women, some of whom are quite diminutive. After marriage the latter frequently become stout, but obesity is rare. The men are a rich brown in color, not so dark nor so reddish as their Navaho neighbors. The women are lighter, many of them being of a fine olive tint, which, with regular features and often with eyes almost oriental in type, make them decidedly comely. Albinism is common among the Hopis and Zuñis, those of the latter tribe averaging one in 200. The hair is thick,

PUEBLO INDIAN VILLAGE.

PUEBLO INDIANS

black, and glossy. That of the men is cut "terrace fashion," that is, banged across the forehead, cut horizontally at the sides on a line with the chin, and allowed to grow to full length behind, but knotted and tied into a short queue. This is probably the more primitive style of hair dressing, but it now varies more or less with the tribe. The front hair of the women is cut level with the chin, parted laterally, and allowed to fall over the face, necessitating continual brushing aside with the hand to permit them to see. The unmarried Hopi girls retain the primitive method of wearing the hair, after reaching puberty, in large whorls over the ears.

Dress.—The costume of the men, now largely superseded by the clothing of civilization, consisted of a shirt, a poncho-like coat formed of a squarish piece with a hole in the middle for the head, and sewed down the sides, with partly open sleeves; a pair of loose trousers reaching below the knees, open half-way up the outer sides and fastened with a belt; footless stockings, leggings, garters, moccasins or sandals, breechcloth, headband, hairband, and blanket. Dressed skin or native cotton formed the chief materials from which their costumes were made, but these gave place largely to woolen articles after the introduction of sheep by the Spaniards. The woolen blanket of later times was probably preceded by a robe made of strips of rabbit or wildcat skin coarsely woven or plaited together. Yucca strips, feathers, and even human hair also formed raw materials for clothing. The typical dress of the women consisted of a skirt of skin or cotton (now of wool) reaching from the neck to below the knees, and girded with a belt, the right arm and shoulder being bare; a manta hanging loosely from the neck and down behind or thrown over the head; stockings, buckskin leggings, consisting usually of an entire skin wrapped many times around the calf, and sandals or moccasins, to which latter the leggings were attached. Among some of the Rio Grande Pueblos the women wear soft buckskin boots instead of the cumbersome leg-wrappings. Necklaces of seashell and turquoise beads and pendants, ear-tablets, bracelets, and other ornaments were worn by both men and women, but the shell necklaces of the latter have been superseded by those of silver. Leather belts strung with large silver disks and silver-mounted wristguards are now worn by the men who can afford them. Excepting the moccasins and leggings, skin has largely passed out of use for clothing, cheap cotton prints and a woolen blanket being almost exclusively employed by the men.

Houses.—The typical pueblo is a many-celled, communal, defensive structure of several stories, opening on one or more courts or plazas in which dances and other ceremonies are performed. When the pueblo enclosed a single court, the outer wall was usually the highest, and was pierced with only small openings, or port-holes, to afford a view of the surrounding country. A slight elevation was usually preferred, but there are many instances in which the site is a lofty mesa or a level plain, while other dwellings were built in natural recesses in the rocky walls of cañons or cliffs, hence their popular designation, *cliff-dwellings*. The site therefore depended on accessibility to water, to cultivable fields, or to the necessity for de-

fense against enemies. Both rounded or polygonal structures were common, while some pueblos were semicircular in ground-plan, with a high rear wall and with the houses arranged in terraces, the tiers of dwellings successively retreating so that the roof of the lower formed the means of access as well as the "front yard" of the tier next above, and so on to the sixth or seventh story. The ground tier usually contained only small wall openings, access being gained by means of a movable ladder to the roof, which was provided with a hatchway. Most of the pueblos still follow this ancient form, but there are now but few whose ground-floor houses are not provided with doors and windows. Sometimes forming a part of and sometimes detached from the main house cluster, are chambers, wholly or partly under ground and usually circular, used as gathering places and sleeping apartments by the men, and still employed for ceremonies and tribal councils. The fireplace was in the centre, the smoke escaping through the hatchway; so hot did these *kivas* become that the Spaniards likened them to stoves, hence their still popular name, "estufas." The structural materials depended largely on the immediate supply. Slabs of sandstone being abundant, were commonly used; they were sometimes neatly pecked and laid in adobe mortar or chinked with spalls, and although joints in the masonry were not "broken," the result was frequently a marvelously straight and strong wall that has stood the ravages of centuries. *Pisé* construction was also employed in massive buildings, such as Casa Grande in southern Arizona. Molded adobe bricks, now so commonly used, were not made in pre-Spanish times, but balls of mud mixed with ashes and sage, and dried, were in vogue as a building material in prehistoric times. The roofs of the houses consist usually of pine or cottonwood beams, with light poles laid transversely, which in turn were covered with brush-grass, and adobe mud, well tamped. The introduction of the horse, which permitted the transportation of heavy roof beams, seems to have had a decided influence in increasing the size of the rooms, the compartments of the ancient structures being usually mere cells. Flakes of selenite were pieced together for window panes, but these have given way to stock frames purchased from the white traders, while the corner fireplace and chimney have been substituted for the central fire pit, except in the *kivas*.

Industries.—As they are sedentary tribes, the Pueblos are agriculturists, their principal crops being corn, squashes, beans, and onions, to which were added wheat, watermelons, cantaloupes, grapes, peaches, etc., on the advent of the Spaniards. Corn is prepared in very many ways, and wild fruits form a not unimportant part of the Pueblo pabulum. Their meat supply was gained mainly through communal hunting, the mountains supplying bear, deer, antelope, and elk, while the valleys and cañons abounded in jack-rabbits, cottontails, prairie-dogs, wild turkeys, quails, doves, etc. The buffalo was probably hunted to some extent by the Rio Grande Pueblos, who also conducted a brisk trade with the Plains tribes up to 25 years ago. For religious reasons, fish was probably universally tabooed, water, on which everything depends, being a sacred element. The turkey was domesticated,

PUERPERAL ECLAMPSIA

and eagles were and still are kept in captivity for their feathers. Cattle, sheep, goats, horses, and asses, which now form such an important part in the Pueblo economy, were unknown before the Spaniards went among them. The Pueblos are a provident people, their reserve food supply usually being sufficient for a year's use, thus succoring them in event of drought. Most of their agriculture is conducted by means of irrigation, although patches of corn, melons, squashes, etc., and small peach orchards are otherwise successfully cultivated in favorable localities. The Hopis raised large quantities of cotton, which they wove into garments and traded with other tribes; indeed they are still the leading cotton weavers among the Pueblos, the industry probably having been introduced by clans from the far south. The Hopis and Zuñis also weave excellent blankets, sashes, dresses, garters, etc., of wool, and a few of the Zuñi men are expert silversmiths. The basket trays of the Hopis are noteworthy, although the art has greatly declined since the introduction of aniline dyes. Some of the other Pueblos make a coarse basket for domestic use. As potters the Pueblos are far in advance of all other Indians north of Mexico: purely primitive methods are still employed and the decorative motive is generally symbolic, intricate, and pleasing.

Social and Religious.—All the Pueblo tribes are composed of numerous clans, named after some animal, plant, or other natural object, and grouped into phratries. Maternal descent is recognized, that is, the children belong to the clan of the mother. Marriage, which is not allowed between members of the same clan, is generally effected by mutual consent of the contracting couple and their parents, and is sealed after an exchange of gifts and a simple primitive ceremony; the vow, however, is not very binding, and divorce is merely a matter of mutual agreement, the offspring, if any, invariably belonging to the mother. The status of the Pueblo woman is high; she owns the house and its furniture, while it is the husband's duty to provide for his family and he frequently makes his wife's clothes. The dead were formerly buried in the houses or beyond the house walls, according to the priestly standing of the deceased; now, however, the dead are buried in a common cemetery in front of the Catholic Church, except among the Hopis, who deposit their dead in crevices in the rocks. The social and religious organization of most of the Pueblos was considerably affected by the Spanish missionary and civil authorities, and among all the tribes except the Hopis a civil governor and other officers are now annually elected, although their power in some instances is only nominal. Originally the religious and social organization was inseparable: each clan had its priest or priest-chief, while both the internal and the external affairs of the tribe, where they affected the complicated and far-reaching religious organization, were controlled by a priesthood. There were also other socio-religious societies, grouped according to the several regions—north, south, east, west, upper, and lower—some of which assumed control over certain affairs in winter, others in summer. The members of these societies, where they still exist, are the medicine-men of the tribe, some of whose functions are the prevention as well as the cure of disease, the regulation of the communal

hunts, the extermination of witchcraft, etc., and the intermediation between the tribesmen and the many nature gods which form the Pueblo pantheon. Communication with these nature powers was and is still conducted by means of secret or open ceremonies, consisting of the depositing of prayer-sticks, chants, dances, sacrifices, pantomime, masquerade, the recital of rituals, etc.

History.—From the Pueblo tribes which have been more intimately studied it has been learned that they consist of many small accretions from various stocks and from many localities, which left their former homes on account of drought and the consequent failure of crops, through superstition, the depredations of enemies, etc. The migrations of these component clans or parts of clans were sometimes very slow, many years being consumed in their journeyings and village after village being successively built, occupied, and abandoned before the final settlement was made. Thus are many of the ruins of Arizona, New Mexico, Colorado, and Utah accounted for. The nuclei of the various Pueblo tribes, however, had their traditional origin in the north, at a place called Sipapu, where they are supposed to return after death, and which is symbolically represented by an opening in the floor of the ceremonial chambers, in front of the altars erected during religious rites.

Indefinite knowledge of a populous region in the north was gained by the Spaniards in Mexico early in the 16th century, and led first to the journey in 1539 of Fray Marcos de Niza to the "Seven Cities of Cibola," the present Zuñi, followed a year later by the expedition under Coronado. This was the first direct contact of the Pueblo Indians with the whites. For the successive Spanish expeditions and the later history of the Pueblos, see NEW MEXICO, and also the subjects mentioned below.

Population.—At the time of Coronado's visit the Pueblo tribes were said to inhabit 66 villages and to number 20,000 men, but it is doubtful if the entire population exceeded this estimate. With the exception of Acoma and Isleta none of the 28 pueblos now existing occupy their 16th century sites, the remainder having been forced into new locations chiefly during the reconquest of New Mexico after the Pueblo revolt of 1680. The present aggregate population of the 28 villages is 10,259. For their distribution see QUERES, SHOSHONEAN, TANOAN, and ZUÑIAN.

F. W. HODGE,
Smithsonian Institution.

Puerperal Eclampsia, a form of eclampsia occurring in pregnant women, usually arising from blood-poisoning and often fatal. The exciting causes may be many, but some form of increased irritability of the nervous system is one of the most important features of the condition. The symptoms come on suddenly, or following a headache, with irritability, and perhaps slight impairment of sight or hearing, or with vomiting. Convulsions of an epileptic, hysterical, or apoplectic variety constitute the main symptom. These convulsions may last for from one to five minutes, and are usually accompanied by unconsciousness. They recur sometimes at very short intervals, most frequently hourly, and many vary from 10 to 30 or more in a day. Such convulsive seizures are always serious to

both mother and child, and prompt emptying of the uterus is the main remedy to be employed.

Puerperal Fever, an infectious disease of women occurring shortly after childbirth, or following a miscarriage, accidental or induced. It is caused by a micro-organism, usually a bacterium (*Streptococcus*), and is communicated by contact with unclean hands, instruments, or clothing which may have brought the infection, just before, during, or after the birth of the fetus. Only in the rarest of instances does it occur when due precautions as to absolute surgical cleanliness have been observed. It usually begins within a week after the termination of pregnancy, ordinarily from the third to fifth day, and is attended with acute inflammation of the reproductive organs, and with septic infection of the blood and body at large. It is always an infection from without, and is preventable by rigid aseptic midwifery. The symptoms will vary very widely according to the infecting organism and the severity of the infection. A slight amount of fever and some local extension of tenderness may be the only symptoms present in mild cases. In septicæmic cases there is usually a decided chill about the third or fourth day, and is attended with acute inflammation of 102° , 103° , 104° , 105° F. with general depression and rapid pulse. The temperature usually remains high and then suddenly drops as the patient recovers. In the severest cases, the pyæmic infections, the blood-current becomes infected: chills, temperature, sweats, occur and recur, and the patient usually dies. The treatment is purely medical, sometimes surgical, and needs the skilled physician and nurse. Prevention is the demand of the modern woman, and she is entitled to it. Unskilled and dirty midwives, unclean doctors, and abortionists are responsible for practically all of the deaths due to childbed fever.

Puerto Cabello, pwār'tō kā-bē'l'yō, Venezuela, port and capital of the state of Carabobo, on a low peninsula jutting into the Caribbean Sea and forming one of the finest harbors in the world. A lighthouse and fortifications protect the entry. Railroads connect the city with Valencia, 22 miles southeast, and with Caracas, 78 miles east. German commercial interests here are strong. The exports are coffee (six sevenths of the whole), cacao, skins, cinchona, oxen, sugar, cotton, and some copper ore. The city was the last stronghold of the Spanish (1823): it was blockaded by the German and British fleets in 1902-3, as the most valuable port of entry and the best place to collect their claims on Venezuela. Pop. (est.) 14,000.

Puerto La Mar, lā mār. See COBIJA.

Puerto Plata, plā'tā, Santo Domingo, port of the Dominican Republic on the north side of the island of Haiti. The entrance to the harbor is extremely narrow: steamship lines connect with Europe, Saint Thomas and Havana, and it is connected by rail with Santiago de los Caballeros.

Industries.— Puerto Plata is the export town of the rich tobacco, sugar, and coffee plantations in the interior of the island, and the annual trade amounts to \$1,500,000. There are several valuable coal mines nearby and there is also an extensive trade in mahogany.

Public Buildings, etc.—A white cheesebox

fort, a relic of the buccaneers, situated upon a small promontory, is the only defense of the town. On one side is the new jail, on the other the barracks. There is the Commercial Club, for the older people, which has a library of 1,000 volumes, and the young men and young women have clubs, occupying commodious buildings. The houses are of modern wood and galvanized iron construction, neatly painted; the streets are straight, clean, macadamized and curbed; and the sidewalks are of stone flagging.

Schools.—The school system is modern and consists of two kindergartens, in charge of trained teachers, two boys' and two girls' primary schools, two normal schools and 15 private schools, assisted by the municipality, some of them teaching English and all planned to do so.

Government.—Municipal authority is vested in a mayor and common council, elected by the people, the mayor being president of the council. The city has a police department, a school board, and is the only city on the island having a street cleaning department; it is well lighted and has waterworks. The city debt is but \$5,000; the annual budget is about \$40,000, of which one third is spent for education.

History, Population, etc.—The town was settled in the first decade of the 16th century by Spaniards. About 30 per cent of the population speak English. Pop. (1905) 5,000.

Puerto Principe, prēn'sē-pā, Cuba, (1) town, capital of the province of Puerto Principe: 170 miles northwest of the city of Santiago de Cuba. It was originally founded in 1515 at Nuevitas, the site of an old Indian village, on the northern coast, but was moved to its present site in 1516. For a time after 1800 it was the seat of government for the Spanish West Indies, and until the end of Spanish rule was an important military post. It is the largest inland city of the island, and is connected with its port, Nuevitas, by railroad. It is the centre of a cattle-raising district, and exports cattle, hides, etc.: sugar also is cultivated somewhat in the vicinity and exported. The town is very mediæval in appearance, the streets are narrow, and the houses old; during the American occupation artesian wells were bored to obtain a pure water supply, the streets were repaired, a good drainage system introduced, and buildings for schools remodeled.

(2) Province, east of the centre of the island, bounded on the east by Santiago de Cuba, and on the west by Santa Clara: area 11,000 square miles. The north of the province is mountainous, the most of the surface being high tableland affording excellent pasturage. The chief industry is cattle raising, which though it deteriorated during the war, is being rapidly revived, and the number of cattle largely increased; the finest horses on the island are also raised here. The province is also well wooded, and lumbering is an important industry: the minerals include iron, copper, and asphalt, all of which are mined to some extent, asphalt being of the most commercial importance. General agriculture is carried on mostly in the vicinity of the town of Puerto Principe, and its port, Nuevitas: sugar is the most important agricultural product. The province was a centre of the insurrectionary movement, and Cubitas in the northern part was the seat of the insurgent government in 1896-8. Puerto Prin-

cipe is the second province of Cuba in size but is least densely populated. Pop. (1899) 88,234.

Puerto Real, rā-āl', Spain, a seaport in the province of Cadiz; on the Bay of Cadiz; seven miles east of the city of Cadiz. The greater part of the town is modern, on the site of Portus Gaditanus, an old Roman place. It has considerable manufacturing; the chief products are leather, pottery, linen goods, cements, vermicelli, and starch. It has a good harbor and an extensive trade; the chief exports are salt, fruit, and manufactures. Pop. (1902) 10,201.

Puerto Rico, rē-kō. See PORTO RICO.

Puerto de Santa Maria, dā sän'tä mä-rē'ä (PORT SAINT MARY), Spain, city in Andalusia, in the province of Cadiz and seven miles north-east of the city of Cadiz; on the Guadalete, near its mouth in the Bay of Cadiz. It is on the railway from Seville to Cadiz. It has a town-house; theatre; a bull-ring, where was given the grand bull-fight to the Duke of Wellington, described by Lord Byron; five promenades, one of them planted with orange and other trees; infantry and cavalry barracks; a custom-house, a good edifice near the mole; a court-house; a parish church in the Gothic style; etc. Leather, soap, hats, wines, liqueurs, etc., are manufactured, and some fishing is carried on. This is one of the Spanish ports from which sherry is exported. Its vicinity to Cadiz, the centre of exchange, is favorable for trade. The principal articles of import are wood and iron. Steam-boats ply regularly between the Puerto and Cadiz. Pop. (1887) 20,590; (1902) 20,115.

Pufendorf, poo'fēn-dōrf, **Samuel**, BARON VON, German publicist and historian: b. Chemnitz, Saxony, 8 Jan. 1632; d. Berlin 26 Oct. 1694. He studied theology and law at Leipsic and in 1657, philosophy at Jena; was tutor in the house of the Swedish ambassador at Copenhagen, and by his work, 'Elementa Jurisprudentiæ Universalis' (1660) secured the appointment, the first in Germany, to the professorship of the law of nature and of nations at Heidelberg in 1661. Here he taught till 1670, and wrote 'De Statu Rei Publicæ Germanicæ,' published in 1667 under the pseudonym of Severinus Mozambano, and which, from the hardy way in which some of the imperfections of the Germanic constitution are exposed, raised a storm of controversy. Partly with a view to escape unpleasant consequences, Pufendorf accepted in 1670 the post of professor of natural law in the university at Lund, offered him by Charles XI. of Sweden. He there wrote his work on natural law, 'De Jure Naturæ et Gentium' (1672), which superseded the former; soon after appeared the abstract of this work, 'De Officio Hominis et Civis' (1673), which has passed through innumerable editions and been translated into several languages. Pufendorf in these works deviated still further than Grotius from the scholastic method of philosophizing, and consequently excited violent opposition. Some years afterward he was appointed secretary of state, royal counsellor, and historiographer at Stockholm. There he wrote in Latin the 'History of Sweden from the Campaign of Gustavus Adolphus in Germany to the Abdication of Queen Christina' (1676), and the 'History of Charles Gustavus' (1606), and in German his 'Einleitung zur Geschichte der vornehmsten

Reiche und Staaten' (1682). These works so much increased his reputation that in 1686 he was called to Berlin as counsellor, historiographer, and judge of the supreme court of judicature. In 1690 he was made privy-councillor of the Elector of Brandenburg, and in 1694 was created baron by Charles XI., king of Sweden. Pufendorf's legal writings are regarded as marking an epoch in the history of natural law, treating it as based upon the social instinct and developing it as a philosophical morality, while allowing scope to revelation.

Puff-adder, one of the names of the American serpents of the genus *Heterodon* (see HOGNOSE); also of the South African death-adder (q.v.).

Puff-balls. See FUNGI.

Puff-birds, a family (*Bucconidæ*) of tropical American picarian birds, resembling kingfishers in form, but living on insects like flycatchers. They are closely related to the barbets.

Puffer. See GLOBE-FISH.

Puffin, a kind of guillemot or auk (q.v.) common on all far northern sea-coasts, where they breed on remote cliffs in large companies. They compose the genera *Fratercula*, *Lunda*, etc., and are distinguished by the large and greatly compressed beak, which is deeply furrowed by three grooves on each side of the mandible. The colors of the beak also add to its singular appearance; this structure being colored bluish-gray at its base, orange-red in the middle, and bright red at the tip. Lastly a large portion of it is annually molted. The body is short, stout, and rounded. These birds excavate burrows in sandy ground, each depositing a single egg of white color. They are able to bite and scratch severely by means of their bills. Puffins swim and dive with great ease; their food consisting of the smaller fishes, and chiefly the young of the sprats and herrings. They are caught and their flesh is salted for food by the inhabitants of the Orkney and Shetland Islands. The appearance of the bill in these birds has gained for them the British provincial names "coulter-neb" and "sea-parrot."

Pug. See DOG.

Pug Mill. See CLAY.

Pug'aree, or **Puggery**, a piece of muslin worn round a hat or helmet in hot climates or warm weather, the ends being left falling down, to protect the head by keeping off the rays of the sun.

Pugatscheff, poo'gä-chëf, **Yemelyan Ivanovitch**, Russian revolutionist: b. Simoweisk, on the Don, Russia, about 1726; d. Moscow, Russia, 10 Jan. 1775. He was leader of a band of robbers in his early youth, served in the Seven Years' war in the Russian, Prussian, and Austrian armies successively, and on his return to Russia was implicated in a seditious movement and imprisoned. He escaped and, prompted by his resemblance to the murdered Peter III., pretended to be the czar. The peasantry flocked to his standard, and were promised relief from their oppressions. His forces constantly increased and success for a time attended him. With 16,000 men in his army he captured Kazan, the old Russian capital, and moved upon Moscow, when he was betrayed by his followers to Suvaroff, captured, and taken

in an iron cage to Moscow, where he was executed.

Puget, Pierre Paul, pē-ār pōl pū-zhā, French painter, sculptor and architect: b. Marseilles 31 Oct. 1622; d. there 1694. He began his career in art as apprentice to a ship-builder named Roman, who set him to carving the figure decorations for the prow and poop of galleys which the prevailing fashion demanded. At 17, however, he gave up this pursuit and traveled to Italy on foot, visiting Genoa, Florence and Rome, and in the latter place entered the school of Pietro da Cortona. This master's influence was always apparent in Puget's painting. In 1643 he returned to Marseilles and to ship-designing. Later he spent six years at Rome in company with a feillant monk on a commission from Anne of Austria to make drawings of antique monuments. After 1653 he painted pictures for churches of Marseilles, Aix and Toulon; but finally abandoned painting on the advice of physicians. His first work as a sculptor, the caryatides supporting the balcony of the Hotel de Ville, Toulon, was a venture into realism, the figures being studied from the porters on the quays. These received the praise of Bernini. He produced two works similarly conceived, 'Hercules Overcoming the Hydra' (now in the Musée de Rouen), and 'La Terre' for the Chateau de Vaudreuil, Normandy. His other works are more in the manner of the Italians of the 17th century, an influence confirmed by another visit at the instance of Fouquet. The fall of that minister put an end to his commission, and Puget settled in Genoa, where he sculptured a 'St. Sebastian and St. Ambrose' for the Church of Santa Maria-in-Carignano and a 'Conception' for the Brignoli, now in the Albergo dei Poveri. His natural restlessness induced his return to France, where he became attached to the arsenal of Toulon as decorator of war vessels. But under the patronage of Colbert he resumed sculpture and executed the 'Milo of Crotona,' 'Alexander and Diogenes' (bas relief), and later the 'Perseus and Andromeda,' all three at present in the Louvre. The 'Alexander and Diogenes' has been called 'the triumph of picturesque sculpture,' though, as Delacroix has pointed out, its subject is one impossible for sculptural treatment as the ray of sunlight which Alexander intercepts can not be represented. His architectural works are not numerous, though he erected the church of the Charité and the Capuchines at Marseilles. Consult: Lagrange, 'Pierre Puget, Peinteur, Sculpteur, Architecte' (1868); Emeric David, 'Histoire de la Sculpture française' (1872).

Puget (pū'jēt) Sound, in the State of Washington, is a large, irregular inlet from the Pacific Ocean. The Sound proper begins at the junction of Juan de Fuca and Georgia straits, and extends south, dividing into two main branches, the eastern one called Admiralty Inlet, and the western Hood Canal. Some of the largest Sound inlets on the east shore are Elliot, Poverty, and Commencement bays; on the west shore, Dogfish Bay and Dye's Inlet, and on the south shore, Carrs, Budd, and Totten inlets. The area of this great landlocked body of water is about 2,000 square miles. It has a number of islands, Vashon and Bainbridge being the largest. A number of rivers, having their headwaters in

the Cascade Mountains, flow into the Sound; the principal river inlets are Duwamish, Nisqually, Nooksak, Puyallup, Skagit, Skokomish, and Snohomish. The Sound has a number of large and safe harbors, and many miles of deep-water front. There is scarcely a sunken rock or reef in the whole body of water. The waters teem with fish; 95 varieties of food fish have been found. The shores are well-wooded, although there has been extensive lumbering in the surrounding forests. The fir is shipped to foreign ports for use in shipbuilding. The cleared lands in the vicinity make most productive farms. Seattle, Tacoma, and Port Townsend are the largest towns on the Sound; but all natural conditions exist for an extensive commerce.

Pughe, pū, William Owen, Welsh antiquary: b. Tyn y Bryn, Merionethshire, 1759; d. 1835. Going to London at 17 he there met the Welsh literary student Owen Jones, and the two published in 1795 the poems of Dafydd ap Gwilym, a 14th century bard. They subsequently edited other Welsh poems, and, assisted by Edward Williams, published the 'Myvyrian Archaeology of Wales' (1801-7). Pughe edited also 'The Welsh and English Dictionary' (1793-1803); the 'Cambrian Biography' (1803); etc. He accomplished not a little in arousing interest in Welsh language and literature.

Pu'gilism. See BOXING.

Pugin, pū'jin, Augustus Charles, English architect and draughtsman: b. Normandy 1762; d. London 19 Dec. 1832. He settled about 1798 in London, where for many years he was assistant to the architect Nash. He subsequently devoted his attention to mediæval architecture, and published 'Specimens of Gothic Architecture selected from various Ancient Edifices in England' (1821-3). With John Britton he published 'Architectural Illustrations of the Buildings of London' (1824). Later works were 'Specimens of the Architectural Antiquities of Normandy' (1825-8) with Le Keux; 'Gothic Ornaments selected from various Buildings in England and France.'

Pugin, Augustus Welby Northmore, English architect: b. London 1 March 1812; d. Ramsgate, Kent, 14 Sept. 1852. He early displayed skill and facility in architectural drawing and acted as assistant to the Grieves in painting scenery for Covent Garden and Her Majesty's Theatre. His taste for Gothic art was turned to account in designing the furniture for Windsor Castle, and in supplying Messrs. Rundell and Bridge with designs for mediæval plate. He became a convert in 1834 to Roman Catholicism, and devoted himself thenceforth to the illustration and revival of Gothic architecture in connection with the Roman Catholic Church. His treatise 'Gothic Furniture and Iron Work' appeared in 1835, and attracted attention. In the following year he published 'Contrasts, or a Parallel between the Noble Edifices of the 14th and 15th centuries and Similar Buildings of the Present Day,' in which he expressed in no measured terms his views as to the decadence of ecclesiastical architecture. Other works of Pugin were 'The True Principles of Pointed or Christian Architecture' (1841); 'An Apology for the Revival of Christian Architecture' (1843); 'The Glossary of Ecclesiastical Orna-

ment' (1844). He was employed by Sir Charles Barry in the decoration of the houses of Parliament, and was connected with Hardman of Birmingham in the manufacture of the renowned Gothic brass-work, besides having a share in the manufactory of stained glass in the same town. Latterly his intellect gave way, from the incessant excitement and labor to which it was subjected, and he was removed to an asylum.

Puisne (pū'ně) **Judge**, in law, a former term for a younger or inferior judge.

Puket, poo-kět', or **Tonka**, a port of Lower Siam, the chief town of Junkseylon or Salang island, on the west coast of the Malay Peninsula. The town is on the east coast of the island at the entrance to a wide and deep bay. It is the seat of the commissioner of the west coast. Its importance is due to its valuable tin mines yielding an annual average of 3,000 tons. Pop. est. 20,000.

Pulangui, poo-lān'gě, river of the Philippines, the upper part of the Grande de Mindanao. See MINDANAO, GRANDE DE.

Pulaski, pū-lās'kī, **Casimir**, **COUNT**, Polish soldier of the American Revolution: b. Lithuania 4 March 1748; d. Savannah, Ga., 11 Oct. 1779. He studied law, served in the army under Charles, duke of Courland, and in 1769 engaged with his father and brothers in the uprising against King Stanislas Augustus. He commanded the insurgents for a time after the death of his father and brothers and in 1771 made an unsuccessful attempt to capture the king at Warsaw which resulted in a sentence of outlawry being passed upon him. Further resistance was soon rendered useless by the coalition of Russia, Austria, and Prussia, and Pulaski made his escape to France where he met Franklin and offered his services to the cause of American independence. He obtained letters from Franklin to Washington and in 1777 joined the army of the latter as a volunteer. He performed distinguished service at the battle of Brandywine and received from Congress promotion to the rank of brigadier-general in command of a division of cavalry. He resigned his command after five months, joined the main army at Valley Forge and received permission from Congress to organize an independent corps of cavalry and light infantry which became known as Pulaski's Legion. In 1779 he marched with his men to join General Lincoln in South Carolina where he performed effectual service. In the siege of Savannah he commanded the French and American cavalry and in an assault on 9 October was mortally wounded and was carried on board the United States brig Wasp in Savannah harbor where he died two days later.

Pulaski, Fort. See FORT PULASKI.

Pulcheria, pūl-kě'rī-a, Byzantine empress: b. 399; d. 453. She was the daughter of the Emperor Arcadius, upon whose death in 414 she became co-ruler with her brother Theodosius II., who was content to leave the reins of power in her hands. With her two younger sisters she took the vow of virginity, as she was determined that there should be no contests between three husbands for the empire. She condemned the Nestorian and Eutychian heresies and was on the friendliest terms with Cyril of Alexandria, Pope Leo the Great, and other great

men of the time. She was a fine scholar, earnest in her devotion to the Church and active in promoting the welfare of her subjects. She arranged the marriage of her brother and after the marriage of his daughter with Valentinian III., she retired for a time from the court. On the death of Theodosius, however, in 450 she again assumed the throne, for state reasons was absolved from her vow of virginity and married the general Marcian whom she raised to the throne as her colleague. After her death she was canonized and her feast is still celebrated in the Greek Church.

Pulci, **Luigi**, loo'jě pool'chě, Italian poet: b. Florence 15 Aug. 1432; d. Oct. 1487. He came of a family in which poetical talents were hereditary; and had two brothers who were also poets, Bernardo, who wrote elegies on Cosmo de' Medici and translated Virgil's Eclogues, and Luca, who composed stanzas on the Tournament of Lorenzo de' Medici. Luigi far surpassed his elder brothers in talent, and became an intimate of the household of Lorenzo the Magnificent. At the instance of Lucrezia Tornabuoni, mother of Lorenzo, he composed an epic poem, 'Il Morgante Maggiore,' based on the tale of Roland, and recited it canto by canto at the table where such men as Poliziano, Ficino, Michelangelo Buonarroti, and Cristoforo Landino gathered. This fact accounts for the diversity of its contents both in respect to the subject matter and the spirit in which it is handled. He assumed the tone of Florentine society at the time of its composition, and inserted at will or to suit the changeable temper of his audiences passages of moving pathos or sincere devotion amid others of coarse buffoonery and broad humor. He fell in with the general Italian tendency of treating the Carolingian legend with less seriousness than did Northern peoples, but he infused a specially bourgeois spirit by his use of many words of the Tuscan dialect. It has been asserted that Shakespeare's familiarity with Pulci is evidenced in his creation of Iago and Othello. Byron was a confessed admirer, and translated the first canto of 'Morgante Maggiore' which he published with 'Beppo' and the 'Vision of Judgment.' See PUNCHINELLO.

Pulcinello, pūl-chī-ně'l'ō. See PUNCHINELLO.

Pulilan, poo-lě'lān, Philippines, pueblo, province of Bulacán, Luzon; on the Quíngua, five miles above its junction with the Grande de Pampanga; eight miles northwest of Bulacán, the former provincial capital. Pop. 10,100.

Pulitzer, pū'lit-sér, **Joseph**, American journalist: b. Budapest, Hungary, 10 April 1847. He came to the United States in 1864 and joined a Federal cavalry regiment, serving till the end of the Civil War; then became a reporter on the 'Westliche Post,' which Carl Schurz had made the leading German newspaper in Saint Louis. Beginning upon the lowest round of a journalist's career, and at first enduring considerable hardship, he rapidly won recognition and rose to the position of managing editor and chief proprietor of the paper. In the meantime he had acquired a knowledge of law, had been admitted to practice and been active in politics in the Republican ranks. He was elected to the Missouri legislature in 1860, was a delegate to the convention of the Liberal Republican party at Cincinnati, which nominated Horace Greeley for president, then

became a Democrat and in 1874 was a member of the Missouri State constitutional convention. In 1876-7 he was Washington correspondent for the *New York Sun*, and in 1878 bought the *Saint Louis Dispatch* and united it with the *Evening Post* as the *Post-Dispatch*. In 1883 he purchased the *New York World*, soon building up a large circulation, and with this journal his name has since been mainly identified. He was elected to Congress in New York in 1885-7 but resigned after a few months. In August, 1903, announcement was made of the endowment of a College of Journalism by him at Columbia University. He has also endowed several scholarships at Columbia College and given largely to other educational and charitable causes.

Pulkova, Russia, village, in the government of Saint Petersburg; about 10 miles southwest of Saint Petersburg. Its fame consists in being the site of the most important observatory in Russia. The place is the home of students.

Pulkova (pool'kō-vā) **Observatory**, in Russia, founded by the Czar Nicholas, and built in 1835-9, is at the village of Pulkova; lat. 59° 46' 18" N., and lon. 30° 19' 40" E. It was intended for the study of sidereal astronomy. The chief instrument, the refractor, with a 15 inch aperture, was not equalled by any other like instrument in the world, until 1870 when the Newhall Observatory (q.v.), in Newcastle, England, secured a 24 inch refractor. Next came the 26-inch refractor for the Naval Observatory (q.v.) in Washington, D. C. In 1885 the Pulkova Observatory erected a 30 inch refractor made by Clark & Sons of Cambridgeport, Mass. This instrument is (1904) excelled by the 36-inch Lick glass, and the Yerkes telescope at the University of Chicago. The determinations of fundamental star places, as made at the Russian Observatory, are regarded as most accurate, and its investigations cover a wide field. The Observatory is not only doing remarkable original research; but it is also a training school for astronomers and geodesists. Doctor Otto Struve has been the director from the beginning. The Repsolds of Hamburg mounted the Russian telescope.

Consult: 'Description de l'Observatoire Astronomique central de Poulkova'; 'Zum 50-jährigen Bestehen der Nicolai-Hauptsternwarte'; 'Publications de l'Observatoire central Nicolas.'

Pul'lan, Richard Popplewell, English architect and archæologist: b. Knaresborough, Yorkshire, 27 March 1825; d. Brighton, Sussex, 30 April 1888. He was educated at Christ's Hospital, studied church architecture and in 1851 was engaged with Wyatt in charge of the decoration of the Byzantine and Gothic halls in the Crystal Palace. In 1854 he visited Sebastopol where he made a model of the country and fortifications, which he exhibited on his return home. He was commissioned in 1857 by the architectural department of the foreign office to examine the Halicarnassus mausoleum and also to make excavations at Cnidus; in 1862 he was engaged in excavating the temple of Bacchus at Teos and that of Apollo Smintheus in the Troad; and in 1869 was engaged in a similar task at the temple of Athene Polias at Priene. He wrote: 'History of the Discoveries at Halicarnassus' (1862-3); 'Byzantine Architecture' (1864);

'Lectures on Christian Architecture' (1879); 'Principal Ruins of Asia Minor' (1865); 'Eastern Cities and Italian Towers' (1879); etc.

Pullè, Giulio, joo-lē'ō poo-lā, COUNT ("RICCARDO CASTELVECCHIO"), Italian dramatist: b. Verona, Italy, 1820. He attained much popularity as a dramatist and among the most successful of his numerous works are 'Romilda'; 'Il Duca ed il Forzato' (1856); 'La Donna romantica' (1858); 'L'Ecole des Femmes'; 'La Donna pallida' (1888); etc.

Pullè, Leopoldo, COUNT ("LEO DI CASTELNUOVO"), Italian dramatist, son of Giulio Pullè (q.v.): b. Verona, Italy, 17 April 1847. He is prominent politically, has held various important municipal offices, is connected with the leading dramatic societies, and as a dramatist has won considerable attention. His publications include: 'Il guanto della Regina'; 'Bere o affogare'; 'Pesce d'aprile'; 'Scene e fiabe' (1889); 'Discorsi parlamentari di Marco Minghetti' (1890); etc.

Pul'len, Henry William, English Anglican clergyman and author: b. 29 Feb. 1836; d. 26 Dec. 1903. He was educated at Marlborough and Cambridge, took orders in the English Church, became a minor canon of York in 1862, and was minor canon of Salisbury 1863-75. He became chaplain of the Alert during its Arctic expedition of 1875-6, and for his services on that voyage was awarded the Arctic medal. He attained a sudden fame by the publication in 1870 of the brilliant 'Fight at Dame Europa's School,' of which 193,000 copies were sold and 14 translations made. He also wrote: 'Modern Christianity a Civilized Heathenism' (1872), the circulation of which reached 20,000 copies; 'The Ground Ash, a Public School Story' (1873); 'The Council of Canterbury' (1882); 'The House That Baby Built' (1874); 'Pueris Reventia' (1893); 'Venus and Cupid' (1896); 'Fred and Fritz' (1898). He edited Murray's 'Handbooks to Italy, Rome, and Greece' (1886-96).

Pulley, a mechanical appliance by which a force applied at one point is transmitted to and acts at another with a change in its direction or intensity, or in both. By its application the power exerted may raise a weight much larger than itself, or impart to the weight a velocity much greater than its own; but, as in the case of all mechanical devices, the energy is merely transformed; never created.

In its simplest form it consists of a wheel of wood or metal which turns on a smooth axle attached to a surrounding frame, usually in the form of a block. The rim of the wheel is grooved so as to allow a rope, cord, or chain to pass around it. Its principle of action is that of reduplication, depending on the fact, first enunciated by Stevin, about 1610, that the tension of a rope is the same at every point.

Under this principle a fixed peg would serve the purposes defined just as well as a wheel, which is introduced for the specific purpose of reducing the amount of friction.

In the single "fixed" pulley, Fig. 1, to satisfy the condition of equilibrium, the tension of the rope must be the same on both sides of the wheel, therefore, the power applied is equal to

PULLEY

FIG. 1.

the weight, and although no mechanical advantage is gained by its use, it serves to change the direction of the force applied, and to obtain a pull on the beam to which it is attached, equal to twice the amount of that force.

In the single movable or "free" pulley with parallel strings, Fig. 2, as in the fixed pulley, the tension of the rope on both sides of the wheel is the same; but, since the weight is supported by two upward forces each of which is equal to the force applied, the power is equal

FIG. 2.

to one half the weight, or in other words, the power that will lift a given weight by the use of a single fixed pulley will lift twice that weight by the employment of a free pulley.

Fixed and free pulleys may be combined in various ways to obtain a mechanical advantage. In the combination shown in Fig. 3, the tension on the beam at (a) is equal to the power applied, and at (b) it is equal to twice that power; but the relation of the power to the weight re-

FIG. 3.

mains the same as in the case of the single free pulley.

If, however, the supporting strings pull at an angle (2ϕ), Fig. 4, the pulley is acted upon by three forces—the weight (w) acting vertically downward, and two equal forces

FIG. 4.

($p \cos. \phi$) acting upward. The resulting effect, $2p \cos. \phi = w$, shows a mechanical disadvantage,

PULLMAN

since the power required increases with the angle, and $p = \frac{1}{2}w$, as shown by Figs. 2 and 3, only when $\phi = 0^\circ$, that is, when the strings are parallel. When $\phi = 60^\circ$, the power is equal to

FIG. 5.

the weight; and when $\phi = 90^\circ$, or $2\phi = 180^\circ$, an infinite amount of power would be required to draw the rope out horizontal.

Combinations of pulleys or compound pulleys are usually arranged according to one of the

FIG. 6.

three systems represented by Figs. 5, 6, and 7, which indicate the action of the supporting forces.

In the first system, Fig. 5, five independent pulleys are supported by an equal number of branches from the main chord. The mechanical advantage stated in terms of weight (w) and power (p) is $w = 2^5p$, or in general $w = 2^np$, when (n) represents the number of pulleys.

In the second system, Fig. 6, the weight is supported by the four forces, $p + 2p + 2^2p + 2^3p = 15p = (2^4 - 1)p$, or in general, $w = (2^n p, - 1)p$.

In the third system, Fig. 7, one continuous string is divided into six branches by six pulleys, and since the tension of each branch is equal to (p) the power applied, $w = 6p$, repre-

FIG. 7.

sents the mechanical advantage, or $w = np$, when (n) is the number of strings rising from the movable pulley. This is the form most frequently used practically, its most extensive application being the block and tackle devices of the running rigging of ships. See BLOCK; TACKLE.

For other examples of the application of pulleys, see TRANSMISSION OF POWER—*Mechanical*.

WILLIAM MOREY, JR.,
Consulting Civil and Mechanical Engineer, New York City.

Pull'man, George Mortimer, American inventor: b. Chautauqua County, N. Y., 3 March 1831; d. Chicago, Ill., 19 Oct. 1897. He learned the cabinetmaker's trade, and during the construction of the Erie Canal he successfully filled contracts for removing various large buildings

in its proposed route. He then settled in Chicago and engaged in building, but devoted much time to the problem of making long railway journeys less tedious, the result being the conversion of two ordinary railway coaches into sleeping cars. They were a success and created a demand for more, and in 1863 he built the "Pioneer" at a cost of \$18,000, which was the first of the cars which have since borne his name. He organized in 1867 the Pullman Palace Car Company, of which he was president, and in 1887 originated the vestibule train. He amassed an immense fortune, founded a model town near Chicago, which he named Pullman (q.v.), and was interested in various other large commercial enterprises.

Pullman, James Minton, American Universalist clergyman, brother of G. M. Pullman (q.v.): b. Portland, N. Y., 21 Aug. 1836; d. Lynn, Mass., 22 Nov. 1903. He was graduated from Saint Lawrence University, Canton, N. Y., in 1860, ordained to the ministry in 1862, held pastorates in Troy, N. Y. (1860-7), New York (1867-85), and Lynn, Mass. (1885-1903). He organized the Young Men's Universalist Association of the City of New York in 1869, of which he was the first president. He was also president of the New York State Universalist Association, and founded the charity known as the "Children's Country Week" in 1882.

Pullman, Ill., a former town, now part of the city of Chicago; on Lake Calumet, 12 miles south of the centre of Chicago. It was founded in 1880 by George M. Pullman, and intended especially for the benefit of the employees of his company. Besides the Pullman Palace Car Company, which is located here, there are car wheel works, a foundry, and other industrial establishments. The town is well built, with wide streets, and several parks; it has a large general retail store, a theatre, a school, and a library. It was formerly under the government of the Pullman Company, but much dissatisfaction arose on account of high charges for water and gas, and in 1889 the town voted for incorporation with the city of Chicago. The company, however, was still the owner of the town and the store; and the exorbitant rents for the poorer tenements and dissatisfaction of the employees with the management of the town were among the causes of the Pullman strike in 1894.

Pulmona'ta, an order of non-marine gastropod mollusks, characterized by breathing atmospheric air; the snails. They are usually small, asymmetrical, and provided with a shell. The sexes are always united in the same individual, and the operculum is always wanting, except in *Amphibola*. The respiratory apparatus, which seems to have been modified from that of ancestors who breathed oxygen mixed with water, by means of branchiae, is not lung-like in structure; it is simply a pouch lined with blood-vessels, and is properly called a pulmonary sac. The terrestrial species will endure deprivation of air for long periods; and the aquatic forms are able to live under water for many hours or days without apparent harm. The pulmonates are divisible into two groups,—one in which the eyes are on the tip of the upper tentacles (as in all the land snails), and another in which the eyes are at the base of the non-retractile tentacles (as in the pond-snails).

Pulo Malagi, poo-lō' mā-lā'hē, an island of the Philippines. See MALAGI.

Pulp. See PAPER.

Pulpit, a piece of furniture, sometimes movable, but as a rule stationary, from which sermons are delivered in a church. The word is derived from the Latin, "pulpitum," a platform or rostrum. Pulpits did not come into use until the 11th or 12th century. Previously to that time sermons were delivered from the rood-loft between the choir and nave, or some other elevated part of the church interior. Pulpits were often splendidly carved, making them valuable examples of art. Among the finest are those of Saint Germain l'Auxerrois in Paris, and Sainte Gudule in Brussels.

Pulque, pūl'kē. This Mexican national beverage is produced from several species of agaves known as majuays (*A. salmiana*, *potatorum*, *Americana*, etc.), which are extensively cultivated on the plains of Apam, in a radius of 50 to 100 miles from the Mexican capital. So extensive is the industry that the plantations of Hidalgo, Tlaxcala, and Puebla, are valued at nearly \$15,000,000, and the railways have transported over 80,000 tons in a single year. On the Mexican railway running to Vera Cruz a special train carries daily \$1,000 worth of pulque to Mexico City, the liquor being transported in goat skins and barrels. When one of these huge plants reaches maturity its tendency is to throw up an immense flower stalk or mast, sometimes 25 feet high, with branches at the top, upon which the blossoms are formed. When a blossom bud appears the plant is ready to yield its juices, which after being collected is the pulque. The plant is "castrated" by making a long incision in the heart or central thickened portion, and the tender leaves of the unopened leaf cluster cut away, the opening being scraped out to form a cavity, into which the juices of the thick, fleshy, expanded leaves, slowly filter. This sweetish, slightly acid liquor is known as aguamiel (honey water) and in its fresh state slightly suggests the odor of root beer. It is removed morning and evening, and can be collected for a month, four quarts a day being the average yield. The collecting is done with a long narrow-necked gourd, with a small hole at either end. The operator places one end in the cavity of the plant, and the other to his lips; withdrawing the air by inhalation, the gourd is filled, and with finger on the hole it is carried to the nearby waiting mule laden with goat skins, and the liquor saved. At the depots the pulque is transferred to reservoirs often made of ox hide, and a little sour pulque added to induce fermentation, when it becomes cloudy. It is universally used by Mexicans, even being sold in the streets in bottles, like milk in this country. There are a thousand places in Mexico City where pulque may be purchased and drunk. The earliest use of the liquor is said to date back to the latter half of the 11th century and to the reign of the eighth Toltec chief, Tep-zucolzin.

CHAS. RICHARDS DODGE.

Pulse (from Latin, *pulsus*, a beating), the rhythmical motion of an artery, with alternate expansion and contraction, in practice considered as a beating. This motion is strongest in the heart (q.v.), which is the centre of the arterial

PULSE GLASS—PULTOWA

system, and from that organ it is propagated through all the minutest branches of the arteries. In those which lie immediately under the skin it can be felt with the finger, as is the case with the radial artery, the pulsation of which is very perceptible at the wrist. The state of the pulse is therefore an indication of the action of the heart and the whole arterial system, and of the condition of the blood and the physical functions in general. The circumstances to be attended to in the pulse are either the number of pulsations which take place in a given time, and the regularity or irregularity of their occurrence, or the character of each pulsation. In the former case the pulse is said to be quick or slow according to the number of pulsations in a given interval; regular or irregular, as they occur at equal or unequal intervals. In the latter case it is strong or weak, hard or soft, full or small, etc. It is affected by the age, sex, and temperament of the individual, and by accidental circumstances, as sleep, food, exercise, heat, etc.

The pulse is most rapid in infancy, making from 110 to 140 beats per minute. During early childhood it makes from 100 to 110, and is regular, and rather soft and small. In youth it is much slower, making from 80 to 90 beats per minute. At this period it is regular, strong, rather soft than hard, moderately full. In mature age the number of beats is on the average about 75 per minute, and the pulse is regular, strong, or moderate, fluctuating between hard and soft, between full and small. In old age the number of beats sinks to about 60. In the female the pulse is more rapid, softer, and smaller than in the male. In persons of a sanguine temperament it is quicker and fuller than in phlegmatic individuals. Sudden agitation and violent passions make the pulse rapid and irregular; joy makes it quick and strong; long-continued grief, languid and soft. The pulse is, therefore, a highly important indication of the state of the system. A deviation from the regular pulse of an individual indicates a disordered state. When the irritability of the system is so heightened as to produce fever or inflammation the pulse is accelerated. If the action of the nervous system is irregular, or unduly heightened, the pulse becomes frequent and irregular. In case of mechanical obstructions to the circulation, as in dropsy of the pericardium, polypus in the heart or in the great arteries, the pulse is irregular and interrupted.

The study of the pulse began with the ancients. Galen wrote several works on it, and for several centuries the subject of pulsation remained much as he left it. The demonstrations of the circulation of the blood by Harvey, and of the irritability of the muscular fibre by Haller threw new light on it, and medical science at last has brought it under full investigation, and has explained it in all its physiological aspects.

Pulse Glass, an instrument invented by Franklin to exhibit the ebullition of liquids at low temperatures. The bulbs are connected by a slender stem and partially charged with water, the supernatant air having been expelled by boiling, and the opening hermetically sealed by a blow-pipe. By grasping one of the bulbs the heat of the hand will cause the formation of vapor and drive the liquid into the other bulb, producing a violent ebullition in the latter.

Pulsom'eter. See PUMPS AND PUMPING MACHINERY.

Pulszky, pŭl'skē, **Franz Aurelius**, Hungarian archæologist and publicist: b. Eperies 1814; d. Budapest 1897. When only 22 he was nominated to membership in the Archæological Institute of Rome. Joining the Liberal party under Kossuth he was elected a deputy to the Hungarian Diet in 1840 and later under-secretary to the Hungarian Prince Esterhazy, minister of foreign affairs in Vienna. He followed Kossuth to England and after the catastrophe of Villagos accompanied the ex-dictator to America. His impressions of this country were embodied in a book entitled 'White, Red, and Black.' Condemned to death by his country for treason, he lived in Italy and joined cause with the Garibaldians. The sentence was removed in 1866; in 1872 he became inspector-general of museums and public libraries. He wrote 'Philosophy of Hungarian History' (1882); 'My Life and Times'; and 'The Jacobins in Hungary' (1887).

Pulteney, pŭlt'nī, **William**, **EARL OF BATH**, English politician: b. London 22 March 1684; d. there 7 July 1764. He was educated at Oxford, and in 1705 entered parliament. He was a partisan of Walpole, and after the accession of George I. was made privy councillor and secretary of war, 1714-17. In 1725 he became a political opponent of Walpole, gained great popularity by his crusade against his former friend, and when Walpole was forced from the ministry in 1742 Pulteney organized under the Earl of Wilmington a new ministry. The public was disappointed in the cabinet, and his acceptance of a peerage further destroyed his popularity. As member of the House of Lords he was not prominent, and when appointed premier in 1746 he held office but two days, being unable to form a cabinet.

Pultowa, pool'tō-vā, or **Poltava**, Russia, (1) capital of the government of Poltava; on the Vorskla River; about 450 miles southwest of Moscow. It is walled and defended by a citadel on a small eminence. It is the commercial centre of a large farm and stock-raising region. The annual fairs, three in number, are of less importance than in former years. Here in 1709 Peter the Great defeated the Swedes under Charles XII. A monument in the principal square commemorates the event; and three miles from the town is the tomb of those who fell in this battle: it is still called the Swedish Tomb. Pop. (1897) 53,060. (2) A government in the southwestern part of Russia in Europe, bounded on the north by Tchernigor, on the east by Kharkov, on the south by Ekaterinoslav, and on the west by Kiev; area, 19,265 square miles. The surface is a plain sloping from the northeast to the southwest, and drained chiefly by the Dnieper and its tributaries. It is one of the most fertile and best cultivated departments of Russia; it exports about one fourth of the whole produce of wheat, oats, and barley of the whole country. Tobacco is increasing in acreage. Stockraising and bee-keeping are given much attention. Manufacturing is limited; the chief products are leather, coarse woolen goods, brandy, and salt-peter. Oil is made from the seed of the sunflower and of flax. Pop. (1897) 2,794,727.

PULTUSK—PUMPS AND PUMPING MACHINERY

Pultusk, pool'toosk, Russian Poland, town in the government of Lomza, on the Narev, about 32 miles north by east of Warsaw. It has several old buildings of historic interest, some manufactories, and considerable trade. It is noted as the scene of the defeat of the Saxons by Charles XII., in 1703, and of the Russians by the French in 1806. Pop. (1902) estimated, 16,000.

Pulvermacher Chain, in electricity, a form of galvanic battery consisting of a series of small wooden cylinders on which a zinc and copper wire are coiled side by side, but without touching each other. The zinc of one cylinder, touching the copper of the adjacent one, forms with it a couple. The whole is immersed in vinegar diluted with water. A chain of 120 couples forms a very powerful battery. See BATTERY.

Pu'ma, or **Mountain Lion**. See COUGAR.

Pum'ice, a variety of lava of a porous and fibrous structure, resembling that of a sponge in appearance, containing from 60 to 75 per cent of silica, with alumina, iron, lime, soda, etc. It varies in color from whitish-gray to yellowish-brown and will float in water. It is essentially lava from which steam or gas has escaped in large quantities while it was being consolidated. Its extreme roughness fits it for use in polishing. In the solid state it is used to polish paint, wood, metal, etc.; and, as a powder, for marble, ivory, bone, glass, and in the composition of tooth-powder. Pumice may be considered because of its glassy composition as a porous variety of obsidian (q.v.). Pumice is obtained in Mexico, Iceland, and Hungary, but chiefly from the Lipari Islands.

Pumpel'y, Raphael, American geologist: b. Owego, N. Y., 8 Sept. 1837. He was educated at the Owego Academy, and later studied sciences and mining engineering in Paris and at Freiberg, Saxony. He made geological investigations in Corsica, and after his return to the United States in 1860 visited Arizona, and in 1861-3 was engaged in scientific explorations under the government of Japan. In 1863-4 he made a private investigation tour through central, western, and northern China and Mongolia, and in 1864 engaged under the Chinese government in examining the northern coal fields. In 1866-73 he was professor of mining at Harvard, State geologist for Michigan in 1869-71, and in 1871-3 directed the State geological survey of Missouri. He was appointed to the United States geological survey in 1879-81, 1884-91, in charge of the Archæan division, and was organizer and director of the Northern Transcontinental Survey in 1881-4. The development of the iron ore industry in Michigan and western Ontario was largely due to his investigations in 1867-1901, and his time is now occupied in organizing and directing an exploration expedition to central Asia. He has published: 'Geological Researches in China, Mongolia, and Japan' (1866); 'Iron Ores and Coal Fields of Missouri' (1873); 'Geology of the Green Mountains' (1894); etc.

Pum'pernickel, the name given to a coarse brown bread made in Germany from unbolted rye. It is baked in large square loaves, which often weigh as much as 60 pounds. Its proper manufacture depends upon the treatment of the

dough, which must contain neither yeast nor leaven, and also on the management of the oven, in which the batch must remain from 12 to 14 hours.

Pump'kin, any of several annual vine-like herbs, especially *Cucurbita pepo*, of the order *Cucurbitaceæ*, probably of tropical America, but not known in a wild state. It is a coarse tendrill-bearing vine frequently exceeding 20 feet in length, with prickly stems and leaf stalks; bears large rough leaves; large yellow flowers, the pistillate being followed by large variously colored but generally yellow fruits, with hard rinds, thick flesh and many seeds. The plant is widely cultivated in warm and temperate countries for its fruits, which range in weight from 10 to 40 pounds, but in some varieties weigh far more. They are largely used for stock feeding and for making pies. The cultivation is essentially the same as for squashes; but in America the plants are most frequently grown in corn fields, the seeds being sown at intervals of about 12 feet, and the plants allowed to shift for themselves after the corn is laid by. It is affected by the same insect-enemies as the squash (q.v.).

Pumps and Pumping Machinery. The term "pump," commonly used to designate the various forms of mechanical devices by which liquids and gases are moved, is of very doubtful origin. It might have been derived from the French "pompe," or the German "pumpe," "plumpfe," or the Latin "plumbum,"—lead, the last-named although advanced by some authorities, appears to be the result of a rather far-fetched conclusion. In its broadest application it designates a multifarious variety of appliances and machines, some simple and others of complicated mechanical construction, which may be grouped into four general classes—"bucket-lifts," "displacement-pumps," "impellers" and "impulse" pumps, according to their mode of action, and disregarding their motive power.

"Bucket-lifts," for raising water from wells or other sources to receiving points above that of the supply, by means of a counterbalanced pole or sweep (swape), and by a windlass or wheel, operated by hand, or with the aid of draught animals, represent the earliest forms of pumps. They were used during the remotest periods, and are commonly used even at the present time, their application not being confined so much to particular localities as to their cheapness and the limited supply of water required. The most primitive device of this character was probably the "cistern-pole." Pliny, 52 A.D., mentions it in his description of the various methods employed in watering gardens. He states: "Water is drawn from wells and tanks by plain poles, hooks and buckets." The "swape" was a natural evolution from the cistern-pole, and in the form of the "shadoof," of Egypt, is authentically recorded as having been in use over 1,500 years B.C., in the time of the Pharaohs, a period antedating the Exodus. It is still used extensively in that region, myriads of them lining the banks of the Nile, where they are worked unceasingly by relays of men, without intermission, day and night. It is also used extensively all over Hindustan, where it is called the "picotah." In fact, the "swape" in some form is used extensively in all of the Ori-

PUMPS AND PUMPING MACHINERY

ental countries from Asia Minor to China and Japan and also in Mexico and South America, for domestic purposes and for the irrigation of land. For the latter purpose, however, it was superseded in India by the "jantu," an oscillating wooden trough involving the same principle, that of the lever, and worked by hand. The "windlass and bucket" arrangements operated by cranks or by tread-wheels, the latter worked by men or animals, appear to have followed the "swape," first among the Chinese, and later among the earliest Greeks and Romans. Tread wheels appear to have been a common mode of applying human and animal effort among the ancients, and are often used even at the present time, although not so much in connection with pumping water. About the beginning of the Christian Era, Vitruvius, a Roman engineer, described a number of pumping machines involving a rotary principle—the "tympanum," "noria," "chain of buckets or pots," the "screw" and the "pump." The tympanum consisted of a series of gutters with their open ends joined to a shaft hollow at one end and placed above the surface of the water at the height to which the water was to be elevated. The gutters thus arranged radially extended to a short distance below the surface of the water which they scooped up successively when the shaft was rotated. Each gutter as it passed above the horizontal position, delivered its water to the shaft to be subsequently discharged through a trough at the desired point. This primitive device continued in use from the remote ages of antiquity up to the 18th century without any change of construction, when La Faye, a member of the Royal Academy of Sciences of France, improved it by substituting a series of curved canals for the original straight gutters, thus developing the progenitor of the "scoop wheel," which propelled by streams, are extensively used for draining purposes. La Faye's improvement and the geometrical reasoning which developed it are exhaustively described by Belidor (Tom. ii. 385, 387). While the tympanum consisted of a series of revolving gutters, the noria may be described as a number of "swapes" arranged around a central shaft like the spokes of a wheel, each swape carrying on its outer end a vessel which fills as the rotary motion of the shaft plunges it beneath the surface of the water, and subsequently discharges its liquid freight into a reservoir placed at the upper part of the circle. It is commonly known as the Persian wheel. The "chain of buckets or pots" was an elaboration of the simple bucket and cord arrangement, by the introduction of a pulley operating an endless rope or chain, to which several buckets or pots were attached. It was employed by all the foremost nations of antiquity, and is still used in many parts of Europe and Asia. Among half-civilized nations it was the highest type of hydraulic machines. Sometimes, when the source of supply was a river, as in the case of the Persian wheels on the Orontes, the driving wheels of the arrangement were placed in the river and propelled by its current. About the middle of the 17th century, European mechanics recognized that when the water was admitted into the receiving vessels of a noria or a chain of pots at the upper part of the circumference, it was converted into an over-shot wheel, thus affording a means of

power transmission to other machines, and in cases where the water supply was limited, but descended from a considerable elevation, it was substituted for the overshot wheel as a prime mover in operating mining pumps, dredging, threshing and other machines of a similar character; while as a conveyor, originally used exclusively as a water elevator, it has also been employed to raise mortar in the construction of buildings, city walls and fortifications, and for carrying grain and flour to the different floors of a mill. In its original form, that of the "sakia" of Egypt, it was unquestionably the pump introduced into Greece by Danaus when he dug the wells of Argos, 1485 B.C., about a thousand years before the building of Babylon by the Persians. Danaus was a brother of the Pharaoh Rameses, who reigned during the period the Israelites were in Egypt. He was compelled to leave that country on account of domestic troubles, and accompanied by his family and friends sailed for Greece. They landed on the coast of Meloponessus, and settled at Argos. According to Pliny (vii. 56), previous to the arrival of these Egyptians, the Greek were unacquainted with wells and pumps; therefore, it is natural to conclude that the wells of Argos dug by Danaus were equipped with the Egyptian pumping devices most adaptable to wells, which was the chain of pots, and not a form of atmospheric or force pump, the pioneer of which is described in Hero's 'Spiritalia' as invented by Ctesibius of Alexandria, one of the most eminent mathematicians and mechanicians of that period, in the year 224 B.C. The most modern refinement of the chain of pots is the "chain pump," while Vera's "rope pump" and the hydraulic belt are applications of the same idea, and consist of endless double bands of rope or woolen cloth passing over two rollers, one placed below the surface of the water, the other at the point of delivery. The rollers are driven at a velocity ranging from one to two thousand feet per minute, and as the bands pass over the upper roller, the water held between them by capillarity is forced out by the pressure and discharged into a receiving chamber connected with the delivery spout.

Machines embodying the principle of the screw, stated by some authorities as invented by Archimedes, the Greek geometrician and greatest mathematician of antiquity, and by others credited to the genius of Canon of Samos, a contemporary of Archimedes, about the year 242 B.C., are described by Vitruvius as of Egyptian origin, and were, according to other authentic records, employed in Egypt, for draining and irrigating land, many centuries before Archimedes visited that country. It consists of one or more flexible tubes of lead or leather, wound spirally around a solid cylinder of wood or iron, the ends of which are pivoted to supports, so that the whole arrangement may be revolved upon its axis, which is generally placed at an angle of 45° to the horizontal. The lower end of the tube is placed below the surface of the water, and the upper end over a receiving trough at the desired elevation. When the machine is rotated the water entering the lowest bend of the spiral is forced upward by each succeeding revolution into the other bends, and finally discharged out of the uppermost into the trough. The Roman screws were made with plank grooves arranged spirally around a solid

PUMPS AND PUMPING MACHINERY

cylinder, and the grooved cylinder thus constructed was fitted into and revolved within a hollow cylinder of the same length.

The connecting link between the various more or less elementary forms of water elevators or "lifts" already described, and the group of hydraulic machines designated as "displacement pumps," is the modern chain pump, consisting of a tube through which the water is raised by a series of pallets or pistons. The pump of Ctesibius appears to have been of this character, although it consisted of only two single-acting pistons working in a cylinder, the water being raised by the up-stroke and expelled by the down-stroke, into a common receiving chamber. In this machine the atmospheric pressure was not taken into consideration, and its capabilities as a water-lifter remained unrecognized until 1643, when Torricelli, the great Italian physicist, announced that water could be raised in a tube by the pressure of air. In 1641, Gallileo, when consulted by a Florentine pump-maker, had failed to demonstrate why water failed to rise in a closed tube above a height of 33 feet under the action of a suction pump. A year or two later, after the death of Gallileo, Torricelli undertook the explanation of that fact, his experiments finally resulting in establishing the law that the heights attained by liquids in a closed tube, the upper end of which was a vacuum, under the pressure of the atmosphere, was proportional to their specific gravities. For example, under these conditions, the height of a column of mercury would be about 28 inches, while that of a column of water would be about 33 feet at the level of the sea. The direct result of this experiment was the invention of the siphon barometer, in which the empty space above the column of mercury is known as the Torricellian vacuum; but, through the further experiments of Pascal, a French mathematician and divine, in 1646, followed by those of Otto Guericke, a philosopher and mathematician of Magdeburg, Prussia, and of Candido del Buono, a member of the Academie del Cimento of Florence, it led to the invention of the "air pump," an apparatus which is described under the title air pump, and which must not be confounded with the atmospheric or displacement pump used for pumping water, which was not unknown to the ancients, and was probably used in some of its innumerable forms, long before the days of Ctesibius. In its simplest form, the modern atmospheric or displacement pump consists of a cylinder (*c*) connected at the bottom with a pipe (*p*), the lower end of which is immersed below the surface of the water. In the cylinder are placed two valves (*uv* and *lv*), the lower stationary and the upper attached to a piston (*f*) at the end of a rod (*r*), which moves the piston up and down under the motion of a handle (*h*). A pipe or spout (*s*), attached to the cylinder near its upper end, receives and discharges the water raised by the working of the piston. Both the valves open upward, and the action of the entire arrangement, based upon the physical fact that two bodies cannot occupy the same space at the same time, is as follows: When the downward stroke of the handle moves the piston upward, the air in the space *A* being rarefied by having to occupy a greater space, and the partial vacuum thus formed relieves the pressure of the atmosphere

from the lower valve, which being opened upward by the pressure of the air in the space (*B*) of the pipe, allows a portion of it to pass into the space (*A*). When the piston descends under the upward stroke of the handle, the air in the space (*A*) is compressed, the lower valve

Modern Displacement Pump.

is closed, and when the density of the compressed air becomes greater than that of the atmosphere, the upper valve is forced open and the air passes into and out of the space (*D*). Thus, by the continued up and down movement of the piston, all the air in the space (*B*) is completely exhausted, allowing the water to rise in the suction pipe under the pressure of the atmosphere upon its surface in the well, until it fills the space (*B*) up to the lower valve. The next upward movement of the piston empties the air in the space (*A*), which is immediately filled with water by the opening of the lower valve. The downward motion of the piston closes the lower valve and forces the water through the upper valve into the space (*D*), from which it is discharged through the spout by the next upward movement of the piston which at the same time refills the space (*A*). Under the laws of fluid pressure established by the experiments of Torricelli and others, the height to which a column of water will rise depends upon the atmospheric pressure at any point on the earth's surface, and varies with the altitude of that point. At the level of the sea,

PUMPS AND PUMPING MACHINERY

the atmosphere exerts a pressure of about 15 pounds to the square inch, and will support a column of water in a closed tube from which the air has been exhausted, between 32 and 33 feet in height, while upon the top of Mont Blanc, or Pike's Peak, 15,000 or 16,000 feet above the sea, the atmospheric pressure will support a similar column of water about 16 or 17 feet in height. A knowledge of this fact is important not only in determining the maximum distance at which the lower valve of a pump may be placed from the surface of the water, but also in every branch of hydraulic engineering. There are numerous forms of displacement pumps. Usually they are equipped with a piston which fits the cylinder tightly and operates as already described. Some forms employ a plunger which but partly fills the cylinder, and instead of driving all the water out of it, merely displaces a volume equal to that of the plunger itself. In others, the displacement is effected by jets of air or steam. In all of them, valves form an essential part. In the simplest forms the valves are made of leather or rubber, and are fixed in position by a hinge on the edge. They are made in a great variety of forms and operate by pressure, or, as in the case of the Reidler valve, a German invention, by mechanical means. They usually consist of a "valve seat," to which the "disk" or valve proper is attached, the "stem" which controls the lift of the disk and prevents its displacement from the seat, the "cover plate," and the "valve spring," introduced in some forms to take up slacks. When a valve is required only to prevent the back pressure or a reverse flow, a single flap or check valve is used. In large pumps a number of small valves are employed, equal in the aggregate to a single large valve of sufficient size to allow the passage of the whole flow, thus preventing injurious shocks when the valves are opened and closed suddenly. Excepting the disks, all the other parts of a valve are made of bronze, while metallic ball and cone valves are extensively used in deep well pumps. The sub-classes into which displacement pumps may be grouped are almost innumerable, but the most important are the "reciprocating" pumps in which the pistons or plungers move alternately back and forth, or up and down, in a straight line, and are designated single-acting when the water is displaced by one part of the stroke, and double-acting when it is displaced by both parts of the stroke of the piston. In a single-acting pump, the water is forced into the ascending pipe only by the downward part of the stroke, and is discharged intermittently, while in the double-acting form, the discharge is continuous, thus saving the power wasted by the ever-recurring acceleration and retardation of the ascending column of water. Of the many methods employed to produce this very desirable result, the most common is that in which an air chamber is fixed vertically on the discharge pipe and receives the water forced upward by the downward stroke of the piston. The air in the chamber being compressed acts as a spring, and returns the force gradually to the ascending column of water as the piston moves upward, thus equalizing the pressure so as to give a uniform discharge. "Direct-acting" displacement pumps are so designated when the motive power is applied in a direct line with the movement

of the piston or plunger, and differentiates them from the "crank-and-fly-wheel," and the "beam pumps," when such devices are employed to transmit the motion. The additional designations—simple, duplex, triple, etc., are applied to pumps according to the number of pistons—one, two, three, or more, operated by a unit of motive power. "Rotary pumps" are equipped with revolving pistons, the axes of which are parallel, and the longitudinal surfaces formed into a series of curves which interlock on the inside and revolve with a tight sliding contact on the outside, against the curved walls of the pump chamber. Screw pumps and chain piston pumps are merely the modern refinement of very old ideas, while the "pulsometer," although one of the latest of modern pumping devices, may be regarded as the connecting link between ordinary pumps and what may be correctly termed "pumping-engines"—machines in which the pump and motive power are combined, the displacement being effected by steam. It consists

Pulsometer.

of two bottle-shaped chambers (a) and (b), the tapering necks of which incline toward each other in a common passage at (c). At the lower end of this passage is a valve (d), which when moved slightly will simultaneously close the opening of the neck of one chamber, and open that of the other.

Water is admitted into the chambers through the passage (e), and valves (f) (g) and forced out through the valves (h) (i), and passage (j) into the air chamber (k). The device operates as follows: Suppose both chambers are full of water and the valve (d) to the right. When steam is admitted to the chamber (a) the water is forced out by direct pressure through the valve (h) into the air chamber (k), so that when the chamber (a) is nearly or quite empty,

PUMPS AND PUMPING MACHINERY

the valve (*d*) moves to the left, cutting off the steam from the chamber (*a*) and admitting it to the chamber (*b*), from which the water is gradually forced out. In the meantime, the condensation of the steam in the chamber (*a*) creates a partial vacuum, and the pressure of the atmosphere on the external water forces it through the valve (*f*) into the chamber, so that when it is nearly full, the air it contains will be sufficiently compressed to force the valve (*d*) over to the right, thus producing a continuous action. The efficiency of pulsometers is equal to that of small direct-acting feed pumps, but they are extensively used on account of their simple construction and great durability.

The expansive energy of compressed air, hot air, and steam, was probably employed by the ancients, as the motive power of pressure engines to raise water, many centuries before the Christian era. There are extant numerous authentic descriptions of devices equipped with piston bellows, employed for this purpose by the ancient Egyptians, Hindus, Chinese, Peruvians and the Aztecs. Also descriptions of hot air devices, and pressure machines operated by steam, the majority of which were contrived by the members of the ancient priesthoods. A great many of these machines are described in the 'Spiritalia' written by Heron, or Hero of Alexandria, a celebrated Egyptian mathematician and physicist, who lived in the 1st century A.D. The water jet apparatus known as Hero's Fountain, although asserted to have been invented by him, was probably an old device at the time he described it. In either case, it is the oldest pressure engine ever described accurately in which a volume of air was used instead of a piston. In 1560, Baptista Porta, an Italian, published a work entitled 'Natural Magic,' in which he described a method of producing a vacuum by the condensation of steam, and its application to devices for raising water. Similar descriptions are given in the writings of Jerome Cardan, also an Italian, published sometime between 1515 and 1570. Therefore, although nothing new was discovered by DeCaus, whose writings were published in Frankfort in 1615, and in Paris in 1624, or by Fludd, Worcester, Savery, and Papin, whose investigations and writings extended over the period from 1663 to 1698, the suggestions afforded by their experiments (subsequently elaborated by Freiburg in 1797, and Shone, Callon, Frizzel, and Pohle, in the period extending from 1870 to 1900), have led to the development of the various forms of modern air-lift pumps operated by compressed air, and pulsometers operated by steam.

Although pressure engines operated by air compressed under a head of water, as suggested by Papin in 1695, had been employed successfully to drain mines as early as 1755, when Hoel employed one in the mines of Chemnitz, Hungary, the application of steam for that purpose did not become an accomplished fact until a much later period. It is, however, interesting to note that the idea was suggested by Lord Bacon prior to 1679, in connection with the English mines, and was probably practically applied to a limited extent about that time. The history of the modern pumping engine, however, more properly begins with the construction of the Cornish engine. Up to the close of the 18th century, the only practical use of steam engines

was in connection with pumping devices, and many notable steam pumping engines had been erected and successfully operated in the mines of Cornwall, England. The various improvements made in this engine from 1800 to 1840 finally culminated in the evolution of one superior type which is now known as the "Cornish." This engine gave highly satisfactory service for the particular purpose for which it was designed—the raising of water out of deep mines where the constantly increasing depth of the shafts necessitated the adaptation of the same engine to the consequent increasing and changing loads. It is constructed upon the principle that the steam within the steam cylinder, is used to lift a weighted pump plunger which after being raised upward to the limit of its stroke, descends slowly by its own weight and forces upward a column of water equal to that weight. The economy produced by the expansion of the steam in the steam cylinder when the steam is cut off during the descent of the plunger is due to the fact, that the pressure and power of the steam first admitted is greatly in excess of what is necessary to lift the weighted plunger. This excess of power is taken up by the weights of the plunger at the beginning of its stroke, and given out at the end when the power of the exhausted steam in the cylinder has fallen below the amount necessary to move the plunger, unless assisted by the power previously stored in it. The length of the stroke of the piston and of the plunger being determined solely by the operation of its steam, equilibrium, and exhaust valves, it is absolutely necessary to maintain the steam pressure at a uniform rate, while the water raised must be received under a uniform head. In mine pumps, the steam cylinder is placed at the top of the shaft, and the pump at the bottom, near the surface of the water. The steam piston is connected to the pump plunger by a beam made of heavy timbers, the weight of which, together with that of the weight of the plunger, forms the weight which, after being lifted by the steam cylinder, raises an equal weight of water when the plunger descends.

In order to preserve the proper relation between the weight of the pump rods and plunger, and that of the water columns, and also keep the engine and pump at the proper speed, by maintaining the proper difference in the weight of the pump rods so as to overcome the friction of their guides, and that of the water in the delivery pipes, a large box, called the "balance bob," in which the adjusting weights in the shape of stones or pieces of iron are placed, is attached to the upper end of the pump rods. When the shafts become deeper, and require the lengthening of the pump rods, the additional weight of the new timbers is counterbalanced by a readjustment of the weights in the "balance bob," thus adapting the engine to the new conditions. In its particular field of application, requiring only a slow action with no demand for uniform flow, it is safe to state that it has never been excelled by any other engine; but, its inordinate size, its action which requires the constant watchfulness of the engineer, its great first cost and expensive repairs, makes it unfit for waterworks, where the water has to be discharged through a long main to a great height above the pump, with a continuous and uniform delivery. The shortcomings of the Cornish en-

PUMPS AND PUMPING MACHINERY

gine, named above, led finally to its complete abandonment for waterworks, and called for a pumping engine that would fulfill the new requirements. This demand was met by the development of the "rotative" engine which, by employing revolving instead of reciprocating pistons, gave a positive motion. The steam power in the cylinder is applied to the pump piston in various ways—through the medium of long or short beams, bell cranks, or gearing, and in some instances, directly through the pistons themselves; in all cases, however, the limit of the stroke of the steam piston and of the pump plunger being governed by a crank on a revolving shaft. Attached to this shaft is a fly-wheel which is designed to assist the crank to pass the centre at each end of its stroke, and also to give up at the beginning of each stroke of the steam piston the excess of power imparted to it beyond that required to move the column of water. The function of the fly-wheel of a rotative engine is exactly similar to that of the weighted plunger in a Cornish engine; both of the devices being applied to their respective

use of steam at the expense of intricate machinery, but require expensive and massive foundations to absorb the shocks produced by their operation, while the momentum of the fly-wheel greatly increases the percentage of possible accidents. The Leavitt engines represent the vertical, and the Holly-Gaskill, the horizontal type.

To follow further the progress of pumping-engine construction up to the invention and development of the "direct-acting steam pumps," which now represent the highest type of pumping machinery, it is necessary to take up the historical thread in the United States. Although steam pumping engines of the direct-acting type, beginning with the device invented by Thomas Newcomen and John Cawley, of Dartmouth, England (which was subsequently improved by Watt, who developed it into an engine of the double-acting type), were in great use for many years; the greatest improvement in this class of pumping engines was made by Henry R. Worthington of New York, in 1840. His invention was the outcome of a long series

Worthington High Duty Pumping Engine.

classes of engines to obtain the best economy in the consumption of steam, the early cut-off resulting in a high grade of expansion, much higher than it was possible to obtain by any other means at the time. They vary greatly in design and in the details of construction, and are made in sizes ranging from those used for supplying water to small towns, up to some of the largest and most expensive machines in the world, and operate either vertically or horizontally. They produce great economy in the

use of steam at the expense of intricate machinery, but require expensive and massive foundations to absorb the shocks produced by their operation, while the momentum of the fly-wheel greatly increases the percentage of possible accidents. The Leavitt engines represent the vertical, and the Holly-Gaskill, the horizontal type. To follow further the progress of pumping-engine construction up to the invention and development of the "direct-acting steam pumps," which now represent the highest type of pumping machinery, it is necessary to take up the historical thread in the United States. Although steam pumping engines of the direct-acting type, beginning with the device invented by Thomas Newcomen and John Cawley, of Dartmouth, England (which was subsequently improved by Watt, who developed it into an engine of the double-acting type), were in great use for many years; the greatest improvement in this class of pumping engines was made by Henry R. Worthington of New York, in 1840. His invention was the outcome of a long series

PUMPS AND PUMPING MACHINERY

gines, nor the balanced beams and weighted plungers of the Cornish. Its action is due to the operation of a piston by a uniform pressure of steam through the entire piston stroke against a uniform water pressure in the pump, the pump piston-speed being governed by the difference between the power exerted in the steam cylinders over the resistance of the water in the pumps, while the length of the steam-piston stroke is limited and controlled by the admission, suppression and release of the steam used in the cylinders. Although steam pumps of this type came immediately into extensive use for feeding boilers, and for supplying moderate quantities of water under medium pressure, the intermittent action of their pump pistons, and consequent irregular flow of water prevented them from being used in waterworks and for other purposes where large quantities of water had to be forced through long lines of pipes. To overcome this serious defect, the same inventor produced the improved pump which is now generally known as the "Worthington direct-acting duplex steam pump." It consists of two direct-acting pumps placed side by side with the piston-rod of each pump connected by a lever to the slide valve of the opposite steam cylinder, so that the movement of each piston instead of operating its own slide valve, as in the single-acting pump, operates the slide valve of the opposite cylinder. The resulting valve motion is such that just before the piston of one pump has finished its stroke, the piston of the other begins its movement. The load of the water column is then taken up alternately and produces a steady flow without serious strains, harshness of motion, and noise, which characterize the action of the single-acting pumps, in which the water column is started into motion at the beginning, and arrested at the end of each stroke of the piston. Although the simplicity of their mechanism, together with the cheapness of their first cost and the certainty of their action, placed them at the head of all the machines of their class, when considered from a mechanical standpoint, the loss of economy in the use of steam continued to militate against their general use for large waterworks purposes. Their light weight prevented the cutting off of the steam in the steam cylinder so as to complete the stroke of the pump piston by the aid of the expansive energy of the steam thus cut off. Therefore the steam applied to move the pistons had to be applied in sufficient quantity and pressure to overcome the weight of the water column and its friction through the pump and connections, at the very beginning of the stroke, and maintained without diminution throughout the stroke, up to its termination, since a falling off in either volume or pressure during any part of the stroke would have stopped the action of the pump instantly. This defect, however, was completely eliminated by applying to them the principle of multiple expansion in the use of steam in compound condensing steam engines. Another steam cylinder was added to the end of the one already in use, and placed in a direct line with it so that the high pressure steam admitted to the first and smaller cylinder after moving its piston was exhausted behind the piston of the large cylinder upon its return stroke. Still further economy was produced in the larger compound engines by using a condenser to create a vacuum in the

large steam cylinder, thus bringing the efficiency fully up to that of the best high-duty rotative engines of the most important pumping plants of the world, their yearly records ranging from 50,000,000 to 120,000,000 duty.

The duty of the Worthington pumping engines was still further increased, and the entire arrangement, from the power-producing to the pumping ends, was made to represent the highest perfection of modern pumping machinery, by the application of the accumulator attachment, a device originally invented by J. D. Davis, in 1879, and perfected by C. C. Worthington, in 1884, and designed to cut off the steam in the steam cylinder at the beginning of the piston stroke, where it subsequently expands and acts as an auxiliary force at the end of the stroke, while at the same time the force exerted by the steam upon the pump plunger remains uniform through the entire stroke. In a compound direct-acting steam pump, it is attached to the plunger-rod which projects through the outer end of the pump chamber. On the end of this rod is fastened a cross-head which moves in guides attached to the outer end of the pump. On this cross-head, and situated opposite to each other, are two semicircular recesses. On the guide plates are two journal boxes, one above and the other below the plunger-rod, equidistant from it, and placed at a point equal to the half stroke of the cross-head. Each journal box carries a short cylinder hung on trunnions, which allow the cylinder to swing backward and forward in unison with the motion of the plunger rod. In these cylinders are plungers or rams, which pass through a stuffing box on the end. The outer ends of the rams have rounded projections which fit into the semicircular recesses on the cross-head, which, as it moves in or out, carries with it the plunger, thus tilting the cylinders backward and forward. These cylinders are called "compensating cylinders." When the engines are used for pumping water, they are filled with water, and when used for pumping oil, they are filled with oil. The pressure on their rams is produced by connecting the cylinders through their hollow trunnions with an accumulator, carrying a ram which moves up and down as the rams of the cylinder move in and out. This accumulator is of the differential type, the small lower cylinder of which is filled with water or oil, in which the ram moves, while the larger upper cylinder is filled with air. On the top of the accumulator-ram is a large piston-head which fits closely in the air cylinder. Therefore, the pressure per square inch on the accumulator-ram is equal to the pressure of the air in the air cylinder per square inch multiplied by the difference between the area of the air piston and that of the accumulator-ram. It is a matter of calculation and construction, which varies according to the particular service for which a pumping engine is designed; while the pressure in the air cylinder is controlled by the pressure in the main delivery pipe with which the air chamber is connected. The effect of this attachment on the successful operation of high duty pumping engines may be briefly described as follows: At the beginning of the outward stroke of the pump plunger-rod, the compensating cylinders point toward the outer end of the pump, with their rams at an acute angle with the plunger-rod, and push-

PUMPS AND PUMPING MACHINERY

ing against its advance under the full pressure of the accumulator load. As the plunger-rod advances outward, the angle between itself and the ram is increased. The rams recede into their cylinders, and their pressure against the rod is decreased until the pump plunger-rod has reached the halfway point of its stroke, when the rams will be at right angles to it—a position in which they neither retard nor advance its movement. As the pump plunger rod continues on its outward stroke, the angle between itself and the rams is again decreased, but now the rams pointing in the opposite direction, emerge from their cylinders, and exert their power to push the plunger outward to the termination of its outward stroke. It is obvious that similar conditions obtain during the return stroke of the plunger, the effect of the action being to store up power at the beginning of the stroke, either forwards or backwards, of the pump plunger, when the steam is under its greatest pressure, and to relieve it at the end of the stroke, when the pressure in the steam cylinder has fallen away to its lowest point, that is, below the amount necessary to move the plunger against the pressure of the water column.

The Worthington pumps are all of the horizontal type, and with this attachment and the use of multiple expansion steam engines, operate with absolute freedom from the noise and shock so characteristic of the crank and fly-wheel machines. Somewhat of an idea of the difference between the first duplex Worthington pumping engines and those of their latest construction may be obtained by comparing that of the Charlestown, Mass., waterworks, with its capacity of 5,000,000 gallons per day, with the installation at the Baltimore, Md., waterworks high service pumping station, which delivers 18,000,000 gallons per day. The former gave a duty of 70,000,000 foot-pounds, while the duty of the latter exceeded 140,000,000 foot-pounds per thousand pounds of dry steam.

The term "duty" represents the work done by a steam pumping engine expressed in millions of pounds of water lifted to the height of one foot by the consumption of 100 pounds of coal, 1,000 pounds of dry steam, or by 1,000,000 British thermal units (B. T. U.). On account of the variable quality of coal, the two last named constants give the more correct results, and are the values now employed in determining the comparative efficiencies of pumping engines, which range from 20.6 per cent for the high-duty engines, to about 0.13 per cent for jet pumps. During the last one hundred years, the development of pumping engines has increased their duty from about 5,000,000 foot-pounds for the Newcomen atmospheric engines, to over 170,000,000 foot-pounds for the crank and fly-wheel, or duplex triple expansion pumping engines of the latest construction.

The "centrifugal pump" is the best known representative of the "impeller" type. It embodies the principle—that a body revolving around a centre tends to move away from it with a force proportional to its velocity: thus the rim of a revolving wheel imparts a portion of its velocity to any substance adhering to it, and throws it off when the force of the velocity thus imparted exceeds the force of adhesion, as the mud thrown off by the wheels of a carriage, or the water from a mop or towel, rapidly revolved by the hand. The first pump of

this type was invented by M. Le Demour, who sent a description of it to the Academie Française in 1732. It consisted of a straight tube attached in an inclined position to a vertical axis, around which it was whirled by a crank-handle. Later forms were constructed by tubes joined in the form of a T, the vertical tube of which was placed in the water. The lower end perforated to admit the water, and fitted with a valve to retain the water in the vertical tube when the pump was not in operation, was placed under the surface of the water and supported upon a pivot. The ends of the horizontal discharge tube were bent down into a circular trough over which they were revolved. When the machine was revolved rapidly the centrifugal force which discharged the water in the horizontal tube was communicated to the water in the vertical, which was also drawn out, but in the meantime refilled by the atmospheric pressure. When it is required to lift large quantities of water to a low elevation, centrifugal pumps may be used with greater efficiency than reciprocating pumps, the efficiency of which diminishes with the lift. A pump of this kind constructed in Massachusetts in 1818, was equipped with four blades set at right angles like those of a fan blower, and was used practically for many years. An improved form was exhibited by Appold in England, in 1851, which embodied all of the principal features employed in the best pumps constructed since that time. It is stated that Appold's pump raised continuously a quantity of water equal to 1,400 times its own capacity per minute. The "whirlpool chamber," designed to utilize the energy developed by the whirling water which in most pumps of this type is lost as eddies in the discharge pipe, was suggested by Thomson (Eng.), and consisted of a chamber somewhat larger than the pump, in which the water discharged by the pump disk, with considerable velocity, was allowed to rotate and impart its energy as an auxiliary aid to the driving power. A pump constructed by him for drainage purposes, in the Barbados, was equipped with a whirlpool chamber 32 feet in diameter, around a pump disk 16 feet in diameter. Others of large size were constructed by Easton and Anderson, for the North Sea Canal, in Holland, which were capable of delivering 670 tons of water per minute to a height of 5 feet; while the Gwynne pumps employed to drain the Ferrarese marshes in Italy, at the junction of the Po di Volano and the minor rivers of lower Lombardy, are capable of a combined delivery of 2,000 tons of water per minute.

A large variety of "rotary pumps," although not involving the principle of centrifugal action, but highly efficient as "low lift" pumps, are represented by the turbine pumps, and the screw pumps. One of the last named type was constructed at Milwaukee to flush the sewage-polluted waters of the Milwaukee River, in 1889. It has a screw wheel 13 feet in diameter, which, revolving at a rate of 60 revolutions per minute, delivers 550,000,000 gallons of water a day on a lift of 4 feet. This water is forced through a brick-lined tunnel 12 feet in diameter, and 2,500 feet long.

"Impulse pumps" operated by the impact of air compressed by a falling column of water or other means, or by the force of a moving column of water suddenly arrested, are represented

PUMPS

by numerous machines, of which the Shone ejector pump, employed to lift sewage, is the best example of the first, and the hydraulic ram, of the second. In the ejector, the compressed air rushes in from the air compressor at the central station and displaces the sewage in the receiving chamber, the falling sewage automatically shutting off the air supply when the chamber is empty.

Hydraulic Ram.

The hydraulic ram, first designed by Whitehurst, a watchmaker of Derby, England, in 1772, and subsequently perfected by Montgolfier, the famous French balloonist, in 1796, consists of a supply pipe (a); an air-chamber (b) attached to the upper side of the pipe (a), and fitted with a valve (c) at the pipe opening; a valve (d) at the end of the supply pipe, and a vertical pipe (e), connected to the air-chamber, through which the water is raised to the desired elevation. The device operates as follows: The valve (d) is made just heavy enough to descend and open the lower end of the pipe (a) when the water filling the pipe is at rest. Now assume that this valve is open, allowing the water in (a) to run out. This water gradually acquires additional momentum, which finally carries the valve up against its seat and closes the outlet. The water in (a) is thus brought to a state of rest and a part of it enters the air-chamber (b) through the valve (c). But, the instant the water in (a) is brought to a state of rest, the valve (d) descends, opens the outlet, allows the water to run out, and is again closed by the increasing pressure, bringing the water to rest and forcing some more of it into the air-chamber, thence through the pipe (e) to the point of delivery. The action of the valve (c) prevents the return of the water from the air-chamber to the pipe (a). This device is of simple construction, may be adapted to numerous locations in every country, and will operate automatically and continuously, without any attention whatever, so long as the surface of the water at the source of supply is kept at the same elevation, so as to insure a uniform pressure against the valve (d). When the perpendicular distance from the source of supply to the valve (d) is small, and the water is required to be raised to a comparatively great height, pipe (a) must be made of sufficient length to prevent the water from being forced back into the source of supply when the valve (d) closes. It is also necessary to maintain the supply of air in the air-chamber, which in time, under the great pressure, becomes depleted by being incorporated with the water. In small rams a sufficient amount of air enters through the valve (d), but in rams of considerable size a small "snifting valve," attached to another chamber immediately below the air-chamber, automatically supplies the additional air whenever it is necessary.

WILLIAM MOREY, JR., C.E.,

Consulting Mechanical Engineer, New York.

Pumps, Compressed Air. During recent years much progress has been made in the art of pumping water by compressed air. At first all systems of lifting water or liquids by means of compressed air were deemed extravagant, but the development of various systems has been such that water may be pumped with marked economy and rapidity by compressed air.

Plunger Pump.—The direct-acting piston plunger pump, of simple or duplex type, is operated with little economy in steam consumption. It is one of the most uneconomical devices known. One hundred and fifty pounds of steam per horse-power per hour is about a fair figure to take for this machine. Experiments have shown that under average conditions hardly 50 per cent of the indicated horse-power of the driving cylinder is utilized in the pump cylinder, the rest being absorbed partly by the engine as machine friction and particularly by the friction of the water in passage through valves and chambers.

The plunger pump consists essentially of two parts, an air end and a water end. The working fluid, which must either be steam or compressed air, operates a piston which transmits its energy through the piston rod which, in turn, causes the pump plunger to reciprocate and thereby pump water. A simple and efficient method for pumping by air in the plunger system is known as the "return pipe" or "closed circuit" system. In this the same air is used over and over again, the exhaust from the pumps being piped back to the compressor under a limited back pressure. In this case the compressed air is a transmitter of power just as a belt or transmission rope, but the air never wears out, may be carried to any distance and at any angle, has little inherent friction, and possesses the highest efficiency in transmission. The system eliminates all trouble from freezing since the air is used repeatedly and moisture once removed cannot be returned. While it requires two pipe lines instead of one, the pipe cost is frequently less because of the smaller pipe size permitted. The pump cylinders will be smaller because of the higher mean effective pressure, and the losses in clearance, often enormous, are entirely eliminated. The great economy in this system is secured in compression, since the scheme is based upon the well-known fact that the greatest losses in compression are thermodynamic, which losses are exaggerated at the lower pressures. For example, 13.42 horse-power will compress 100 cubic feet of free air to 60 pounds pressure, starting at atmospheric. This same energy will compress 100 cubic feet of free air to 350 pounds,

PUMPS

when beginning compression at 60 pounds, giving on the return pipe system 290 pounds available pressure with 60 pounds back pressure. A reheater on the pump will secure additional economy. Losses through leakage and transmission are supplied by a small "booster" compressor.

Another method of securing high economy is to employ compound or triple pumps, reheating the air after each expansion. This may reduce the air consumption to $\frac{1}{2}$ or $\frac{1}{3}$ its value in the simple pump of the same capacity. In some cases this same result may be secured by the use of three pumps in series, reheaters being used as before after each expansion and the exhaust from one pump being supplied to the next, with a larger air cylinder.

Displacement Pumps.—The displacement pump is almost the essence of pumping simplicity and, if its first promises were borne out, it would be a most powerful factor in pumping problems. As it is, within its recognized field, it has shown a fitness which qualifies it especially for the work. In brief, it consists of two barrels or cylinders which are filled and discharged alternately—the charge in each cylinder being directly discharged or displaced by the admission of the required volume of compressed air through a valve automatically controlled.

The fundamental requirement is a complete submergence of three to six feet. The cylinders are filled at no expense of power and discharged with a minimum of friction losses. Dirt, sand, or grit will not interfere with its operation. Such a pump starts and stops automatically and uses air exactly in proportion to the amount of water discharged. It will run for weeks without attention and requires practically no repairs. Standard sizes have capacities up to 1,500 gallons per minute.

The height to which these pumps will lift water is limited only by the air pressure used, and by an arrangement of several pumps in series almost any height may be attained with ordinary moderate air pressures. In mine work the displacement pump is especially useful in handling accumulated water in sumps, dips, entries, etc. It is also peculiarly effective in subways and tunnels, in automatically discharging the seepage or leakage water which accumulates. It may also serve in the basement of factories and warehouses which are subject to occasional inundations by floods or high water. The same apparatus, but in slightly modified form, is employed for elevating acids and heavy chemical solutions or for pumping marl, paints and other semi-fluids. In this case the air valve is so located that it is not affected by contact with the liquid or by the corrosive fumes arising therefrom. The capacity of the displacement pump is determined by the size of the cylinders or chambers and the volume of air available. Employing air at ordinary pressure from a common single stage air compressor with a lift not exceeding 250 feet, the efficiency of the displacement pump is higher than that of the usual direct-acting plunger pump under the same conditions of lift and pressure. There are three distinct types of these pumps known as the Latta-Martin, Halsey, and Harris or "return-air."

The Latta-Martin system employs two tanks, side by side, with a valve arrangement

controlling the admission and discharge of water and air. In operation the pump is completely submerged and one cylinder fills by gravity while air is forcing out the water from the other. When this cylinder is empty, the air is automatically released, water enters and compressed air is applied to empty the other cylinder. The discharge water flows continuously.

The Halsey system employs a single tank and must be submerged to insure good operation. The tank fills by gravity, and as the water enters it causes the float to rise, which, when near the top of the tank, drops a valve and permits the influx of compressed air to discharge the water. The flow of water is intermittent. Neither the Latta-Martin nor the Halsey system uses compressed air expansively, and as a result there is considerable energy lost.

The "return-air" system overcomes the difficulty of not employing air expansively and in it no floats and no air valves, outside the engine room, are employed and the same air is used over and over again, thus eliminating the effect of clearance. This system employs two tanks and its operation consists in brief of turning air out of one tank and forcing it into the other, and in so doing will draw water into the former and force it out of the latter. The charge of air in the system is so adjusted that when one tank is empty the other is full, and at that moment the switch will be automatically thrown, reversing the pipe action and thereby reversing the action of the tanks. Of all systems of pumping, the Harris is certainly the most economical and efficient. Using the air expansively, all the inherent energy of compressed air is used, and no mechanism being submerged, there is no chance for the system to become inoperative due to breakage or a demand for repairs. This system may be employed for pumping mixtures of sand and water, and operates with a marked degree of economy and reliability.

Power Driven Pumps.—The greatest advantage in the use of the power driven pump, when the air is the driving fluid, lies in the fact that it permits the expansive use of the compressed air, resulting in a considerable saving and economy. Power pumps consist essentially of expansive air engines, which may be either direct connected, belted or geared to some form of duplex or triplex plunger pump, or to the simple, compound or turbine types of centrifugal pump in its various forms. Compressed air is supplied to the air engine from some distant air compressor and this air engine, when specially designed for the use of air involving considerations of air valves and low clearance, operates with efficiency and economy. Where the magnitude of the operation justifies it, the use of the "return pipe" system with expansive engines will, in connection with reheaters, secure the very highest efficiency.

Air Lift.—Opinions differ as to the theory of the air lift. A common air lift is one where we have a driven well in which the water is approximately near the surface. We place in this well a large pipe for the discharge of the water. This is known as the "eduction pipe." This pipe does not touch the bottom of the well, but is lifted above it so as to admit freely the water through its lower end. Alongside this pipe, either on the outside or within, is a second but smaller pipe, properly proportioned

and intended to convey compressed air to a point near the bottom of the eduction pipe. The air pipe is connected with an air receiver on the surface, which is in or near the engine room in which free air is compressed. Before turning on the air the conditions in the well show water at the same level on the outside and inside of the eduction pipe. At the first operation we must have sufficient air pressure to discharge the column of water which stands in the eduction pipe. This goes out *en masse*, after which the pump resumes a normal condition, the air pressure being lowered and standing at a point corresponding with the normal conditions in the well. This is determined by the volume of water which a well will yield in a certain time and the elevation to which the water is discharged. It was first supposed that in all air lift cases the water was discharged because of the aeration of the water in the eduction pipe due to the intimate commingling of air and water. Bubbles of air rising in a water column not only have a tendency to carry particles of water with the air, but the column is made lighter, and, with a submergence or weight of water on the outside of the eduction pipe there would naturally be a constant discharge of air and water. This is known as the Frizell system, and where the lifts are moderate, that is, where the water in the well reaches a point near the surface, it is very likely that the discharge is due to simple aeration.

Most air lift propositions are deep well cases, that is, the water is lifted a distance greater than 25 feet. Aeration will not expel such water, so the idea of piston-like layers of air and water is developed. The economy of the air lift system is in direct proportion to the capacity of the well to form these piston-like layers, and the reason why they are formed is that after the first discharge, there is kept up a constant struggle between the air under pressure and the head of water on the outside of the pipe, each one seeking to enter the lower end of the eduction pipe.

When the air pressure is greater than that due to the head of water, a certain volume of compressed air is admitted into the eduction pipe. The water is at that time moving rapidly, that is, its momentum has been established. The air takes up this velocity and goes upward with the water. If a sufficient quantity of air has been admitted in proportion to the diameter of pipe, and if there is a sufficient pressure in this pipe to prevent the free discharge of the air, it is readily seen how this bubble of air spreads itself across the diameter of the pipe in a piston-like condition. The reason why this piston is not elongated and continuous is that the free discharge of the air, aided by the velocity with which everything in the eduction pipe is moving, causes a fall in the air pressure just sufficient to allow the water head to press the water into the air space, or the open end of the eduction pipe. In other words, as the air pressure is slightly lower, the water pressure, which was nearly equal to the air pressure, becomes a little greater and the piston-like layer of water enters the pipe, shutting off the air. This "chunk" of water rises in the eduction pipe with velocity equal to that of the air, and as it has plugged off the air nozzle, there is a momentary rest, during which the air has a chance to accumulate greater pressure, and just

as soon as this pressure overcomes that of the water, the conditions are reversed and another "chunk" of compressed air is discharged into the pipe, shutting off the water for an instant. This process is continuous and as regular as the movement of a pendulum.

As these "chunks" of air approach the surface, they are gradually enlarged, because of the reduced load upon them, and it is likely that before they reach the surface there is a general breaking up of the piston-like layer condition. The Pohlé system of air lift is probably the best known. Sand, grit and small stones are no obstacles in the satisfactory operation of this system. As a matter of fact, in many instances, the capacities of the wells have been increased by opening up the well more thoroughly, by removing sand. Water pumped by this system is purified, due to aeration. The system is not limited as to the quantity of water that can be handled. This will depend upon the capacity of the wells to furnish the water. The height of the lift is unlimited, as well as the submergence.

EDWARD F. SCHAEFER, M.M.E.,
Ingersoll-Rand Company, New York.

Pun, a play upon words alike or similar as to sound, but different as to sense. The pun has been familiar to all literatures, and in ancient times was used even in a serious context. This was true also in England of the 17th and 18th centuries. Puns are met with in the tragedies of Shakespeare; in the works of the quaint Fuller; in the discourses of Bishop Andrewes. The divines of colonial America did not lack for them. Mathey Byles won his reputation for wit chiefly through the appositeness and felicity of his puns. Thus, being a sturdy loyalist, he was for a time kept under surveillance by a sentinel whom he called his "observe-a-Tory." A parishioner called upon him, and Byles, noting his ulcerated jaw, sent him to Copley, the artist, to have his tooth drawn. Among famous English punsters may be cited Sydney Smith, Lamb, Theodore Hook, Wilberforce, and, above all, "Tom" Hood, most inveterate and happy of the coterie, who even remarked of a certain undertaker that he appeared anxious to "win a lively Hood." The pun has frequently been derided as an unworthy form of wit. John Donne is reported to have said that "He who would make a pun would pick a pocket"; and Holmes, in the 'Autocrat,' after denouncing verbicide, gives a pyrotechnic display of excellent puns. It is true, however, that the pun has found advocates in divines, philosophers, statesmen and literati. Many puns convey a weight of meaning which could hardly be secured by sentences of paraphrase.

Punch, a well-known English comic weekly, the most famous journal of the kind. The success of Philipon's Paris 'Charivari' induced a staff of several Englishmen—some, as Douglas Jerrold, Thackeray, and John Leech, since famous—to organize for the publication of a 'London Charivari,' of which whole pages of text had been set up, when the scheme collapsed. This undertaking had, however, some indirect influence on the subsequent 'Punch.' The idea of 'Punch' appears to have been due originally to Ebenezer Landells, a Northumbrian wood engraver and draughtsman, and to have

been developed by Henry Mayhew, a brilliant humorist of the time. "Mr. Punch" was the traditional jester of the puppet-show transformed into "the laughing philosopher and man of letters; the essence of all wit, the concentration of all wisdom." As finally agreed, Mayhew, Mark Lemon, and Stirling Coyne were to be co-editors, Landells was to find drawings and engraving, and Douglas Jerrold and Gilbert à Beckett were to be among the outside contributors. The first number appeared on 17 July 1841. In two days two editions, each of 5,000 copies, were sold out. After some early vicissitudes, 'Punch' became an English institution. A list of its writers and artists includes many famous names besides the jovial Lemon and the caustic Jerrold; Thackeray, "Tom" Hood, Charles Lever, "Tom" Taylor, Cuthbert Bede, Horace Smith, Shirley Brooks, F. C. Burnand, Artemas Ward, G. A. Sala, H. W. Lucy; John Leech, H. K. Browne ("Phiz"), Sir John Tenniel, George Du Maurier, Stacy Marks, Sir John Millais, Linley Sambourne, and others. The editors have been: Mark Lemon, 1841-70; Shirley Brooks 1870-4; "Tom" Taylor, 1874-80; Sir F. C. Burnand, 1880-1906; and Owen Seaman, 1906-. 'Punch' has done much to laugh out of court various shams, fads, affectations, and forms of ostentation. In British politics it has remained wholly free from party bias. The present application of the word "cartoon" originated with 'Punch,' the occasion being the first great exhibition of cartoons for the Houses of Parliament (July 1843), when Mr. Punch appeared with a rival series of sarcastic designs. 'Punch' has sometimes been unfairly attacked for its insularity. Consult: Spielmann, 'The History of "Punch"' (1895); 'An Evening with Punch' (1895), selections from the first 50 years; A. W. à Beckett, 'The à Becketts of Punch' (1903).

Punch, a beverage, commonly composed of wine or spirits, water, lemon juice, and sugar, with occasionally an addition of some spice, as nutmeg or cinnamon. These are usually mixed in the requisite proportions in a large bowl made for the purpose—hence called the punch-bowl. The beverage is compounded as follows: Squeeze the juice out of three or four lemons into a jug, adding thereto the peel of one lemon cut in slices, 12 ounces of lump sugar, and three and a half pints of boiling water; infuse this mixture for half an hour, then pour into the punch-bowl, and add of rum and brandy rather less than a pint of each. Varieties of punch are called after one of their principal ingredients, gin, milk, orange, raspberry, tea, wine, etc. Punch was introduced into Great Britain from India, and it appears to be so called from the Hindu *punch*, five, which is the usual number of the ingredients.

Punch. See METAL-WORKING MACHINERY.

Punch and Judy, in Great Britain and some European countries, a well-known puppet-show frequently exhibited in the streets. The show of Punch and Judy derives its origin from the Neapolitan Punchinello, but many of its features are purely English. The earliest account of the adventures of Punch and his wife, Judy, is found in a ballad, the date of which does not appear to be anterior to 1795. This account corresponds pretty closely with the representa-

tions given in our streets. The show embodies a domestic tragedy, followed by a supernatural retribution, the whole of which is treated in a broadly farcical manner. Punch himself is represented as short and thick-set, with an immense hump upon his back, a wide mouth, long chin, and hooked nose, and wearing a three-pointed cap. His wife, Judy, who is in some respects his counterpart, and his dog, Toby, are important characters in the performance. See also PUPPET-SHOWS.

Pun'cheon, a liquid measure of capacity containing from 84 to 120 gallons. See WEIGHTS AND MEASURES.

Punchinello, pŭn-chĭ-nĕl'ō (from *pulcinello*), an Italian mask or marionette. The Abbate Galiani derives the name from a misshapen but humorous peasant from Sorrento, who had received it (about the middle of the 17th century) from his bringing chickens (*pulcinelle*) to market in Naples, and who, after his death, was personated in the puppet-shows of the San Carlino theatre, for the amusement of the people, to whom he was well known. See also PUPPET-SHOWS.

Punctuation, from the Latin *punctus*, "a point," is the term used to designate the use of certain points, or marks, for the purpose of separating words from each other in sentences and parts of sentences. The convenience of such separation is too obvious at this time to need support by argument, but the fact is, nevertheless, that for many centuries after writing had first been used there was nothing to indicate the pauses, or divide a book into sentences. No attempt to punctuate is apparent in the earlier manuscripts and inscriptions of the Greeks. It was in Alexandria that punctuation originated, when that city was the centre of ancient learning. The open space to the left of a line which indicates the beginning of a paragraph made its appearance on papyri at Alexandria. The early signs intended for punctuation were at first used in poetry only, to enable readers to comprehend the meaning hidden in obsolete words and involved and difficult verses. Ages passed, however, before any form of punctuation became general, and it was not until the 9th century after Christ that the division of sentences by full-points and colon and semi-colon marks, took place. The comma was the same as to-day, a large dot or double dot indicated the full-stop, and a high dot stood for a colon or semi-colon.

Modern punctuation has no hard and fast rule, and this is especially the case in English, writers of standing exemplifying the broadest latitude in this respect. Some long sentences in standard works are carried through without a comma, while in books of equal repute commas are plentifully used where no pause is apparent. Properly speaking a comma signifies a slight turn in a sentence; the semi-colon is used where there is a change too important for a comma, and the full-point or period marks the close of a sentence. The colon is not often used, and when it is used it is where, as a rule, a full-point would be better. This may also be said of the semi-colon. There is a growing tendency to uniformity in the use of punctuation.

Pun'dit, or **Pandit**, an Indian title for men who devote themselves to the pursuit of learning, especially on religious subjects. It corre-

PUNIC WARS — PUNJAB

sponds with the modern title of "Doctor." It is especially applied to certain men who in the 19th century after being instructed by the English in the science of geodesy have explored and surveyed Tibet, and other areas of Asia generally inaccessible to Europeans. The most notable of them were Mohammed i Hamid, who went (1863-4) over the Karakoram Pass to the Yarkand River; the famous Naing Singh, who, between 1865 and 1875, brought back valuable results from his travels in Tibet, and discovered the northern springs of the Indus; Mirza Sudja, who (1868-9) crossed the Little Pamir to Kashgar and Ley; Haider Schah, who in 1870 made an expedition to Faizabad in the valley of the Oxus, and later explored the mountain ranges between Cabul, Bokhara, and East Turkestan. Consult: Garbe, 'Indische Reise-skizzen' (1889).

Punic (pū'nīk) **Wars**, in ancient history, the general name applied to three great wars between the Romans and the Carthaginians. The first (264-241 B.C.) was for the possession of Sicily, and ended by the Carthaginians having to withdraw from the island. The second (218-202 B.C.), the war in which Hannibal gained his great victories in Italy, was a death struggle between the two rival powers; it ended with decisive victory to the Romans. The third (149-146 B.C.) was a wanton one for the destruction of Carthage, which was effected in the last-named year.

Pu'nica. See POMEGRANATE.

Pun'ishment, a term which originally signified pain inflicted on or endured by a person as a satisfaction or atonement by him for some offense which he had committed; it embodied, in fact, the idea of retaliation, and this appears to have been the earliest notion of punishment which most nations possessed. It occurs among the early Greeks; the Romans recognized it in the laws of the Twelve Tables; and it was the principle of the well-known provision of the Mosaic law, "an eye for an eye," etc. In this country punishment by death is called *capital punishment*. See CAPITAL PUNISHMENT; LAW, CRIMINAL; PRISON; etc.

Punjab, pūn jāb', or **Panjab** (Persian, "Five Waters"), an extensive territory in the northwest of Hindustan, formerly under the dominion of the Sikhs, but in 1849 annexed to British India. It is so called from its position, being intersected by the five great rivers which unite to pour their waters into the Indus. In 1901 the northwestern part of the Punjab was separated to form a chief commissionership under the government of India (see NORTHWEST FRONTIER PROVINCE). The lieutenant-governorship as thus limited is bounded on the east by Kashmir, Tibet, and the river Jamma; on the south by Sind and Rajputana, the river Sutlej being in part a boundary river; on the west by Baluchistan and Northwest Frontier Province; on the north by the Northwest Frontier Province. For administrative purposes it is divided into four divisions (Delhi, Jalandhar, Lahore, and Rawal Pindce). Lahore is the capital, with a population of 202,064. Delhi has a population of 208,575, while Amritsar, the sacred city of the Sikhs, has 162,429. Simla, the mountain capital, is within the Province, and is the residence of the viceroy during the hot season. Murree is

the summer headquarters of the military command. The total area of the province is 97,209 square miles, with a population of 20,330,339. The area of the Native States is 38,299, with a population of 4,438,816 at last census in 1901.

General Description.—The province of the Punjab is a triangular tract of land between the Sutlej and the Indus, and, with the exception of the hill country on the slopes of the Himalayas, it is a great alluvial plain. On the northeast side is the margin of the Himalayas, on which there are beautiful sanatoria, or hill stations:—Simla (the mountain capital of India), Dagshai, Sabathu, Kassauli, Dharmasala, Dalhousie, and Murree, the military headquarters of the province. The country between Jhelam and the Indus is known as the salt range, as it contains inexhaustible mines of rock salt which have been worked for many centuries. It is abundantly irrigated by six rivers. These rivers (proceeding from west to east) are the Indus, the Jhelam (ancient *Hydaspes*), Chenab (ancient *Acesines*), the Ravi (ancient *Hydraotes*), the Beas (ancient *Hyphasis*), and the Sutlej (ancient *Hesudrus*). The Jhelam and Chenab unite their waters, and then are joined by the Ravi; the united stream is then augmented by the Sutlej, which has previously received the Beas. The combined waters of these rivers form the Panjnad, which joins the Indus near Mithankot. The rivers of the Punjab divide it into five districts, or *doabs* (countries between two rivers): namely, the Sind-Sagar Doab, between the Indus and Jhelam; the Jech Doab, between the Jhelam and Chenab; the Rechna Doab, between the Chenab and Ravi; the Bari or Manja Doab, between the Ravi and Beas; and the Jallandar Doab, between the Beas and Sutlej. Of these the first is by far the largest, but also the most sterile and least inhabited, abounding with bare eminences and rugged declivities, interspersed here and there with rich and fertile valleys. The second is mostly level, and has been described as "a sterile waste of underwood," the abode of shepherds, and scantily irrigated; the Rechna Doab is bare and neglected, though susceptible of high cultivation; the Bari Doab, though bare, has a large surface under cultivation, and is the most populous and important of all, containing the large towns of Amritsar, Multan, and Lahore; while the Jallandar Doab is highly cultivated, well peopled, and excelled in climate and productions by no province in India. Speaking generally, the plains east of Lahore are the most fertile, wealthy, and populous of the province, and the granary of the Punjab; while those on the west present a striking contrast. The soil of the level country varies remarkably from stiff clay and loam to sand, mixed with each other in variable proportions, and with vegetable matter; besides which, carbonate and sulphate of soda are sometimes mixed with it in such quantities as to render the land almost worthless. The mineral wealth of the Punjab is almost confined to its rich deposits of rock salt. The climate is hot and dry, and little rain falls, except in the higher country and under the influence of the Southwest monsoon. The part of the province to the east of Lahore can be cultivated in most seasons without irrigation, but owing to this its crops are much more likely to fail from a deficiency of rainfall than those of the western irrigated tracts. The summer heat is

very great, and in the early part of January sharp frosts are common.

Vegetation, Agriculture.—Wood is scarce, except upon the hills. In the west considerable areas are occupied by date-trees; and palms of other species, banyans, and other trees are found here and there. The area under forests is over 4,250,000 acres. About 28,000,000 acres of the remainder are under cultivation, and over 20,000,000 acres more are available for cultivation. The principal grain crops are wheat, barley, rice, buckwheat and millet, pease, vetches, and mustard; sesamum and other oil seeds, turnips, carrots, onions, cucumbers, and melons. Indigo and sugar are exported. The tobacco plant grows luxuriantly, especially about Multan, and opium has been grown pretty extensively. About 7,750,000 acres are under wheat, and over 750,000 under rice. The total irrigated area exceeds 9,000,000 acres, of which more than half is irrigated by canals. Among the fruits are the date, orange, fig, vine, apple, mulberry, banana, and mango. The live-stock include sheep, cattle, horses, and camels; buffaloes are common.

People.—The population of the Punjab is composed of various races, the chief of which are the Jats, Rajputs, and Pathans. The Jats form the bulk of the agricultural peasantry, and are tall and athletic, with handsome, open countenances, long beards, and fine teeth. The people, generally, are in physical respects superior to those of Bengal. The native states subordinate to the Punjab government are thirty-six in number. Thirty-one are Hindu and five Mohammedan. The most important is Kashmir, the next Patiala. The Mohammedan state of Bahawalpur is the next. The next in order are Kapurthala, Mandi, Sarmur, Faridkot, and Malarkotla. The other states are insignificant in rank and consequence.

Religion.—The religion of the Sikhs, which is the national religion of the Punjab, was founded by Nānak, who was born A.D. 1469. The Golden Temple at Amritsar is the centre of the faith and the guardian of the sacred book known as the *Adi Granth* (see *SIKHS*). By the census of 1891 the distribution of the population according to religious profession was as follows: 12,915,643 Mohammedans, 10,237,700 Hindus, 2,100,000 Sikhs, 53,909 Christians, 45,683 Jains, 6,236 Buddhists, 412 Parsis, 33 Jews, and 30 others. Of the Christian population 27,915 belonged to the Church of England, 12,083 were Presbyterians, 7,113 were Roman Catholics, the remainder being Baptists, Methodists, etc. The American Presbyterian Board of Missions has important stations at Lahore, Ludianah, and Umballa. Lahore is the seat of both a Church of England bishop and a Roman Catholic bishop. The Mohammedans form a very large part of the population of the Rawal Pindee and Multan divisions. The Hindus predominate in the easterly divisions and in the mountainous district of Kangra. The Sikhs reside chiefly in the centre and east of the province and constitute the mass of the gentry. The few Buddhists of the Punjab are almost entirely confined to the small Spiti district in the extreme northeast. The Pathans and Baluchis are the most numerous of the Punjab Mohammedans by race, but the Mohammedan strength consists largely in converted Hindus belonging to the Jat and Rajput tribes. The Hindu Jats form a large proportion of the population.

Language and Education.—The chief languages spoken in the Punjab are Punjabi (known as Gurmukhi), Hindi, Sindhi, Jataki, Kashmiri, Pushtu, Persian, and English. Since the country came under British rule elementary education has received much attention. The total number of educational institutions in the Punjab in 1899-1900 was 7,867, with a total of 262,319 scholars. Of the higher educational institutions of the province the following may be mentioned:—the Punjab University at Lahore; Lahore Government College; Oriental College; St. Stephen's College, Delhi; Lahore Medical School; St. Thomas College, Murree; the Khalsa College, Amritsar; Bishop Cotton School, Simla; and the Lawrence Military Asylum, Sanawar.

Manufactures and Trade.—The manufacturing industry of the Punjab is chiefly confined to the larger towns. Amritsar, Lahore, Multan, and Shujabad are distinguished for their silk and cotton fabrics, and the silks of Multan called *kais*, and chiefly used for scarfs, possess a strength of texture and brilliancy of color for which they are much prized in the Indian markets. The shawls of Lahore, too, rank only second to those of Kashmir. Brocades, tissues, and carpets resembling the Persian are also manufactured in the capital. In the east of the Punjab white cotton goods are prepared of a stronger and more durable texture, as well as cheaper, than those of British manufacture. The Punjab enjoys from its position an extensive transit-trade. The imports comprise sugar, spices, and other groceries, dye-stuffs and cottons, woolen and silk fabrics, metals and metallic utensils, cutlery, precious stones, ivory, glass and cochineal, asafetida, safflower, fresh and dried fruits, wool, horses, etc. The exports—partly of home produce, partly in transit—comprise grain, *ghee*, hides, wool, silk and cotton fabrics, carpets and shawls, raw silk and cotton, indigo, tobacco, hardware, horses, etc.

Government and Revenue.—The province is under a lieutenant-governor, assisted since 1897 by a legislative council of nine members. The most important item of revenue is the land-tax, which, on the average, yields a net revenue, after deducting charges, of nearly £2,000,000; besides there are excise duties on spirits and drugs, duties on stamps, etc. The financial condition is so favorable that there is often a clear surplus of revenue over expenditure of £2,500,000. About one-half of the whole cultivated area of the Punjab is tilled by owners, and about one per cent. by tenants paying a nominal or no rent. Of the remaining area one-fifth is cultivated by occupancy tenants, and the rest is held by tenants-at-will, a class increasing in numbers from year to year. Rents vary from 5 annas to 40 rupees per acre, the average being about 2 2-3 rupees. On about two-thirds of the land held by tenants-at-will the rent is wholly or partly paid in kind, and the average rent payable in kind is for the whole province about two-fifths of the produce. Nearly 5,000,000 acres are under mortgage.

Army and Police.—The Punjab forms a military district called "The Northern Command," under a lieutenant-general with headquarters at Rawal Pindee. The military authority of this officer extends to the Northwest Frontier Province. The military cantonments are Rawal Pindee, Peshawar, Noroshera,

Abbottabad, Sialkor, Jhelum, Lahore, Jullundur, Sirhind, Umballa, Ferozepore, Kohat, Bannu, and Murdan under a lieutenant-general. The military force stationed in the Punjab in 1900 consisted altogether of 68,806 men. Of cavalry there were 11,893, of infantry 50,504, of artillery 6,120, with some engineers, etc. There were thus more troops in the Punjab than in any other division of India. The police force is stated to be in a most effective condition. It numbers about 20,000 men, divided into two divisions, the Trans-Sutlej and the Cis-Sutlej. Almost all the police are armed either with swords or guns. The Punjab has a chief court with five judges, two of whom are natives—and four temporary judges.

History.—The Punjab plays an important part in the history of Hindustan and British India. It was invaded in 327 B.C. by Alexander the Great, who defeated Porus at Mong in Gujerat and overran the whole country. In 1022 it was overrun by the troops of Mahmūd of Ghazni, whose successors held the country for 170 years, making Lahore the seat of their government. In 1193 it passed by conquest into the hands of Mohammed Ghorī, and Delhi became the capital. After his death the country was ruled by a succession of turbulent chiefs, principally Afghans, till at length in 1526 Baber, the founder of the Mogul Empire, having obtained possession of the country, ascended the throne, and established a dynasty whose sway prevailed for about two centuries, during which the Sikhs were rising into importance. In 1738 Nadir Shah overran the Punjab, and in the following year he defeated the Mogul army at Karnal and sacked Delhi. The Sikhs were utterly defeated by the Afghan conqueror Ahmed Shah Durani in 1762, and the Moguls nominally ceded the Punjab to him. The Durani dynasty maintained its ascendancy till the beginning of the 19th century, when the Sikhs under Ranjit Singh began their career of conquest. In 1818 this renowned chieftain stormed Multan and took Peshawar—in the following year conquering Kashmir and Derajat west of the Indus; and in 10 years he succeeded in establishing his power over the whole country. In 1839 Ranjit Singh died. His son Khorak Singh quietly succeeded, but died of a decline a few months after his father, on which Shere Singh, a natural son of the great Ranjit, assumed the sovereignty, but was assassinated 15 Sept. 1843. Dhulip Singh, the reputed son of Ranjit Singh, succeeded his brother. This young prince was converted to Christianity and retired on a princely pension to England, where he died. But from the close of 1843 to the period of its annexation to British India the government was in abeyance, or, what is worse, in the hands of an ignorant, bloodthirsty, rapacious, and insubordinate army. At length it became manifest that the Sikhs of the Punjab were preparing for an irruption into the territories protected by the British on the east of the Sutlej. In the end of December 1845, the Sikh forces passed the Sutlej into the territories protected by the British, with a most formidable train of artillery, but they found themselves completely worsted after the hard-fought actions of Mudki, Ferozeshah, Aliwal, and Sobraon. Lahore and other stations were afterward occupied by British troops; the Jalandar Doab, between the Sutlej and Beas, was

permanently ceded to the British; and the province of Kashmir, and the other provinces of the Himalayas, were vested in the Rajah Gholab Singh. In 1849 a conspiracy between several disaffected chiefs and the Afghans resulted in further hostilities against the British, Multan being the centre of their operations. The indecisive battle of Chillianwalla was followed by the capture of Multan in January, and the victory of Gujerat in February 1849, since which period the former territories of the Sikhs have formed an integral part of the British Empire. The most important subsequent event in the history of the province was the Indian Mutiny, when the Sikhs were loyal to the British government, and the present Sikh regiments of the British native army form the most important section of the military strength of the empire, the Sikhs and the Gurkhas being esteemed by many critics the finest soldiers in the world. After the suppression of the Mutiny the province was erected into a lieutenant-governorship under Sir John Lawrence, the distinguished statesman.

Bibliography.—Consult Cunningham, 'Archæological Survey of India,' Vol. XIV. (London 1882); Gore, 'Lights and Shades of Hill Life in the Afghan and Hindu Highlands of the Punjab' (London 1895); Latif, 'History of the Punjab from the Earliest Antiquity to the Present Time' (London 1896); Medicott, 'Sketch of the Geology of the Punjab' (Calcutta 1888); Prinsep, 'History of the Punjab'; Griffin, 'The Rajas of the Punjab' (2d ed., London 1872); Honigberger, 'Thirty-five Years in the East'; Edwardes, 'A Year on the Punjab Frontier'; Clark, 'Thirty Years of Missionary Work in the Punjab.'

Pun'j'nod, or Panjnad ("the five rivers"), a stream of the Punjab, formed by the Sutlej, Beas, Ravi, Chenab, and Jhelam, whose waters it carries to the Indus (q.v.), about 490 miles from the sea near Mithankot. The Punjnad bounds Punjab and Bahawalpur in part of its course.

Punk'ah, a large fan used in India and other hot countries for ventilating rooms. It consists of a movable frame of wood covered with canvas and suspended from the ceiling. It is pulled backward and forward by means of a cord, and thus causes a current of air in the apartment.

Punnah, pūn'a. See PANNA.

Puno, poo'nō, Peru. (1) town, capital of the department of Puno; on the west shore of Lake Titicaca, 12,870 feet above sea-level, and 90 miles east by south of Arequipa. It has two churches, a college, and a hospital. A railway runs to Arequipa and to Mollendo on the Pacific. Pop. 6,000. (2) The department of Puno; area, about 41,198 square miles, is mountainous. The principal crops are potatoes and barley, but it is particularly distinguished by the extent of its pastures, cattle raising being the chief occupation. Its principal exports are the wool of the sheep, llama, alpaca, and vicuña, and some cascarilla bark from the valley of Carabaya. Pop. (1896) 537,345.

Punt, poont, an ancient country on the Red Sea, whether in Asia or Africa is disputed. The country is mentioned a number of times in the Egyptian hieroglyphics, and such records show that the Egyptians obtained from Punt

ostrich feathers, leopard skins, gold, incense, ivory, precious woods, and various ornaments. There are good reasons for locating Punt where is now Somali Coast and Abyssinia. Accounts are given of journeys to Punt, undertaken by command of monarchs. Queen Hatshepsut sent thither a whole fleet, and the account of the voyage, the persons and places seen in Punt were recorded on the walls of the Temple of Deir el-Bahri. Consult: Müller, 'Asien und Europa'; Naville, 'Deir el-Bahri'; Eрман, 'Life in Ancient Egypt.'

Punt, an oblong flat-bottomed boat used for fishing and shooting in shallow waters. The most common mode of propulsion is by pushing with a pole against the bottom of the river, or stream, a process which is hence called punting.

Punta Arenas, poon'tā ā-rā'nās, or **Sandy Point**, Chile, port and capital city of the territory of Magellan, at the extreme end of Patagonia (lat. 53° 10' S.), and lying in a plain bounded by the rivers Las Minas, on the north, and La Mano, on the south, with wooded hills back of the river. The city is Chile's only free port and is a coaling station for steamers passing through the Strait of Magellan. The surrounding country produces rye, barley, potatoes, etc., and the forests supply timber which is exported to the Falkland Islands. The seal-fisheries are considerable. The city has banks, stores, hotels, and an opera house. Pop. (est.) 6,400. The site was made a penal colony in 1843, and a town was founded in 1849.

Punxsutawney (Punk-sōo-tā-nŭ), Pa., city in Jefferson County; situated on Mahoning Creek and on the Pennsylvania & N. W., the Buffalo, Rochester & Pittsburg, and the Buffalo & Susquehanna R.R.'s; about 70 miles east of Pittsburg. It is the business centre of a great bituminous coal and coke region and the headquarters of the second largest producers of bituminous coal and coke in the United States. There are also large iron furnaces and numerous smaller industries. Punxsutawney is an Indian name signifying "Mosquitotown" or "Gnatopolis," the Indian word for blood-sucking insects of the genus *Culex* being "ponki." It was organized into a borough in 1849. Its growth since 1890, when it had a population of 2,792, has been rapid. Pop. (1900) 4,375; (1905, estimated) 7,348, and with the borough of Clayville immediately adjoining it on the west, 10,520. W. O. SMITH.

Pupa, the name applied to the second stage in the metamorphosis of insects. In the typical complete or holometabolic insects, exemplified by beetles, the *Lepidoptera*, flies, etc., the pupa stage is marked by quiescence and rest, and thus presents a contrast to the preceding and active larval stage. During the pupa stage the elements of the larval form are being remodeled into that of the *imago* or perfect insect, which in due time emerges from the pupa case. An insect may remain in the pupa stage from a few hours or days to weeks, months, or even years.

The pupæ of the hemimetabolic insects, or those which undergo an incomplete metamorphosis (such as grasshoppers, locusts, bugs, etc.), are called nymphs, and differ from the perfect insect, which they resemble in form, chiefly in the absence or rudimentary nature of the wings. These latter structures in the pupa state of hemimetabolic insects may generally be per-

ceived to be in course of formation, the perfect insect or imago state being characterized simply by the full development of the wings. See INSECTS; METAMORPHOSIS.

Pu'pin, Michael Idvorsky, American scientist and inventor: b. Ildvar, Hungary, 4 Oct. 1858. He came to America in 1874, was graduated at Columbia in 1883, and as the first American holder of the John Tyndall Fellowship of Columbia studied physics and mathematics at Cambridge University and under the famous von Helmholtz at the University of Berlin, here taking his degree of Ph.D. He returned to teach at Columbia, was appointed adjunct professor of mechanics there in 1892, and professor of electro-mechanics in 1901, which position he now (1904) holds. He is the inventor of an improvement in the telephone by means of which it is confidently expected telephoning across the Atlantic will soon be rendered practicable. Professor Pupin first announced the theory underlying his invention in March 1899, and brought his system to such perfection that in 1901 it was acquired by the Bell Telephone Company and by German telephone interests for practical trial. In June 1903 the device had been found, in Germany, to operate successfully over a cable more than 260 miles in length, and its applicability to submarine cables was considered established. His invention not only makes it possible to telephone much further than before, but renders all messages more distinct. It consists, essentially, of self-inducting coils of wire placed at intervals about the wire which transmits the sound, thus preserving the vibrations a greater distance. He has published: 'Thermodynamics of Reversible Cycles in Gases'; etc.

Puppet-shows, an amusement or entertainment popular in Europe. One of the most common classes of puppets is called, in French, *marionnettes*. These are images of the human figure moved by wires or threads on a stage, and made to perform little dramas, the dialogue of which is carried on by the person in concealment, who moves the figures. In the common street performance in England of Punch and Judy (q.v.), however, the performer puts his fingers in the figures. Puppet-shows were common among the Greeks, from whom the Romans received them. Xenophon, Aristotle, Gellius, Horace, and others mention them. Such exhibitions, which are so pleasing to children and the uneducated, naturally passed through various degrees of perfection in different ages, and even now exhibitions of puppets are common in some countries which display great mechanical ingenuity. Clocks often display movable puppets, and it is not unfrequent in Germany to find on ancient town-clocks puppets which move whenever the clock strikes. In 1674 there was a puppet opera at Paris, which met with great applause. At present there are two theatres in Paris for puppet-shows, and they still continue to be performed in several large cities of Italy. In Germany, also, excellent puppet-shows are sometimes seen, but they are there hardly ever stationary, and are not by any means so much patronized as in Italy. There is a puppet-show in the Italian colony in New York, which is much patronized by Americans.

Puracé, poo-rā-sā', a volcano of the Andes in Colombia, 20 miles east of the town of

Popoyan. Eruptions have occurred several times; the town of Puracé at the base of the mountain was destroyed by the eruption of 1827; and the top of the volcano blown off and its height reduced to 15,420 feet by the eruption of 1849. It is still active, and hot vapors issue constantly from the crater.

Puranas, poo-rā'ṇas. See SANSKRIT LANGUAGE AND LITERATURE.

Purbeck (pér'bèk) **Beds**, a series of geologic beds or strata consisting of limestones, clays shales and sandstones which in England form the uppermost member of the Jurassic system (q.v.). They are named after the Isle of Purbeck on the southeast coast of Dorsetshire where they are exceptionally well developed and yield among other building stones a limestone, susceptible of a good polish, which is known as Purbeck marble. The "Isle" is in fact a peninsula 12 miles long by 7 miles broad, almost completely surrounded by sea. The Purbeck beds appear in a chalky ridge which traverses the island from west to east.

Purbeck, Isle of. See PURBECK BEDS.

Purcell, pér'sèl, **Henry**, English composer: b. London 1658; d. 21 Nov. 1695. He was the son of a musician of the chapel-royal, who left him an orphan in his 6th year. He was admitted a chorister in the king's chapel, where he studied music under choir-master Cook and his successor Pelham Humphrey, and afterward under Dr. Blow. In 1676, when only 18, he was made organist of Westminster Abbey, and six years afterward was appointed to fill the same office at the chapel-royal, St. James. From this period his fame increased rapidly, his anthems and other church music being popular in all the cathedrals of the kingdom; nor were his compositions for the stage and music-room less successful. He composed music, religious and secular, with equal facility; and with respect to chamber music his compositions superseded all prior productions. Of his numerous works his 'Te Deum' and 'Jubilate' were composed for the celebration of St. Cecilia's Day, 1694. Of his instrumental music a collection was published two years after his decease, and comprised pieces in four parts, for two violins, tenor and bass. Many of his songs were published after his death under the title of Orpheus Britannicus. 'Ye Twice Ten Hundred Deities,' contained in this collection, is considered the finest piece of recitative in the language; while his music in 'King Arthur' has maintained its popularity undiminished till our own day. In 1695, the year of his death, he set to music 'Bonduca,' an opera altered by Dryden from Beaumont and Fletcher; but his chief opera is 'Dido and Æneas' (1680). He was the author of a vast variety of catches, rounds, glees, etc., remarkable both for their melody and for their spirit, humor, and originality. He was buried in Westminster Abbey. A splendid edition of his works is published by the Purcell Society, founded in 1878. An earlier edition of his sacred compositions is that of Novello (1829-32). Consult: Cummings, 'Life of Henry Purcell' (1882).

Purcell, John Baptist, American Roman Catholic archbishop: b. Mallow, County Cork, Ireland, 26 Feb. 1800; d. Brown County, Ohio, 4 July 1883. He came to the United States in

1818, was educated at Mount Saint Mary's College, Emmitsburg, Md., received minor orders, and later studied at Saint Sulpician's College in Paris. He was ordained in 1826 and in 1827 appointed to the chair of philosophy in Saint Mary's College, of which he became president in 1828. In 1833 he was consecrated bishop of Cincinnati, and at once set about the improvement of the diocese under his charge, and in 1846 the number of churches under his control had increased from 12 to 70, the number of Roman Catholics from 6,000 to 70,000. He founded schools and academies, built a convent for the Ursulines, and in 1847 the diocese of Cleveland was formed out of that of Cincinnati at his request and placed in charge of another prelate. In 1850 he was made an archbishop and in 1851 received the pallium from the Pope's own hands. He founded Mount Saint Mary's of the West, destined to become one of the leading theological seminaries of the country, and in 1855 presided over his first provincial council. New sees were formed from his diocese in 1868, but though their creation had limited his diocese in extent, it still contained 140,000 Roman Catholics. He attended the Vatican Council in 1869 and celebrated his golden jubilee with great rejoicing among his people in 1876. In 1879, however, his hitherto unbroken prosperity was interrupted. His brother Edward had been appointed his vicar-general and the financial affairs of the diocese had been left by the bishop entirely in his brother's care, trusting implicitly in the latter's financial ability, which was unfortunately as little as the bishop's own. When the crash, rendered inevitable by faulty business methods, came, Edward died broken-hearted. The indebtedness reached nearly \$4,000,000, and the crisis came at a time of general financial panic. The bishop, however, was never accused of any dishonesty, though the unwisdom of his confidence in his brother was widely criticised. His own light regard for the value of money was well known, as he had served as bishop for 25 years before he accepted even the "cathedraticum" of \$5,000 a year, and when paid it usually was given away before night. He tendered his resignation in 1880, but it was not accepted though he was given a coadjutor. At his death the Roman Catholics in his original diocese numbered half a million. He published a series of text-books for the use of Roman Catholic schools in his diocese.

Purchas, pér'chas, **Samuel**, English author and Anglican clergyman: b. Thaxted, Essex, about 1575; d. London September 1626. He was graduated from Cambridge, took holy orders, was vicar of Eastwood, Essex, 1604-13, and in 1614 became rector of Saint Martin's, Ludgate, London, where he remained until his death. He published in 1613 'Purchas his Pilgrimage, or Relations of the World and the Religions Observed in All Ages and Places,' supplemented in 1625 by 'Purchas his Pilgrimages' in four volumes. The first is his own work and the latter a collection of the narratives of different travelers, edited by him. The latter was illustrated with maps, and the edition of 1626 was supplemented by a fifth volume. It was a work of great value in its day, giving accounts of travels in Europe, Asia, Africa, and America, and was soon imitated. It is valuable to-day as revealing the ideas prevailing in England at that time

concerning the rest of the world at large. He also wrote: 'Microcosmos, or the History of Man' (1619); 'The King's Tower and Triumphal Arch of London' (1623).

Purdue University, the Indiana State college of agriculture and technology at Lafayette. It was established under the land grant act of 1862; and in 1869 was named for John Purdue who gave \$150,000 and 100 acres of land to the State for the institution. It was first opened to students in 1874. Its present organization includes six schools: (1) the School of Mechanical Engineering; (2) the School of Civil Engineering; (3) the School of Electrical Engineering; (4) the School of Agriculture; (5) the School of Science; (6) the School of Pharmacy. The regular courses extend over four years; in addition the School of Agriculture offers a special two years' course, and a short course of two winter terms; and the School of Pharmacy also offers a two years' course. In 1902 a course in telephonic engineering was added. The degrees conferred are bachelor of science, and graduate in pharmacy. Graduate work is provided for and the degrees of master of science, mechanical engineer, electrical engineer, civil engineer, and analytical chemist are given to graduate students. Instruction in military science and tactics is a part of the curriculum, and all men students are expected to join the military company for two years. The college is coeducational, women entering mostly the schools of Science, of Pharmacy, and of Agriculture. The grounds comprise 180 acres, 50 of which are used as the university campus, the remaining 130 being devoted to the experimental farm for the School of Agriculture. In 1902 a new agricultural building was completed furnished with the best modern apparatus, in 1903 the Eliza Fowler Hall was completed, containing the auditorium and the offices of the president; other buildings of importance are the engineering building for the departments of Mechanical and Civil Engineering, the electrical building, Science Hall, the veterinary infirmary, Purdue Hall, and Art Hall. The laboratories are all well equipped with modern scientific appliances, the equipment of the School of Mechanical Engineering including a locomotive testing plant. The library contains (1904) 12,300 volumes. The agricultural experiment station is also connected with the University, and farmers' institutes are organized throughout the State. Tuition is free for residents of the State; the income is derived mostly from the land grant fund of 1862, from the national appropriation and from the State tax; in 1903-4 it amounted to \$319,612. In 1903 the students numbered 1,339; the total number of graduates 1,861. Its rank among schools of technology is high, and it holds an influential place in the educational system of the State.

Pur'gatives, cathartics; medicines for evacuating the bowels. See CATHARTIC; CONSTIPATION.

Pur'gatory, according to the doctrine of the Roman Catholic Church, a state or place in which the souls of those who depart this life in the grace of God suffer for a time, in expiation of their venial transgressions or in undergoing the penalty due to mortal sins, the guilt and eter-

nal punishment of which have been remitted. Hence purgatory is not a place or state of probation; for the souls in purgatory the time of probation is past, and they are already assured of their everlasting bliss in heaven, though as yet they are not sufficiently pure and holy to be admitted to the vision of God. The dogmatic teaching of the Church goes only so far as to declare that, (1) there is a purgatorium (place of purification), and (2) that the souls therein are aided by the prayers of their brethren on earth. But though the definitive teaching of the Church stops here, the speculations of divines, the meditations of spiritual men, and the beliefs of the general mass of the faithful go much further, and have developed an idea of purgatory which is very much more definite. Thomas Aquinas and Suarez, among the greatest lights of the theological schools, teach that instantly after passing out of the present life, the faithful souls are cleansed from the stains of all venial sin by their turning with perfect love to God; at the same time the debt of the temporal penalties of sin, whether mortal or venial, has still to be paid. It is the common belief of the Western Church that the purgation is by material fire, and the teaching of theologians is that the purgatorial pains are very terrible. While confessedly the doctrine of purgatory is not clearly and unequivocally deducible from any passage of the universally accepted books either of the Hebrew or the Christian Scriptures (for Macabees is not received by all as canonical, and passages of the New Testament which Catholics believe to point decisively to this doctrine have no such signification for Protestants), it is admitted on all sides that in the very earliest church liturgies that are extant are found forms of prayer for the dead, and that the existence of an intermediate state after death is taught by the Fathers both Eastern and Western with practical unanimity, so far at least as to admit that the dead can be aided by the prayers of the living.

Purification, in the Jewish ceremonial law, a bodily cleansing with water accompanied by rites more or less elaborate according to the nature of the uncleanness from which the person was to be purified: this physical cleansing being regarded as emblematical of an inward spiritual purification. For different occasions of purification and different rites, see Leviticus xi. 25-40, xv. 1-15, xv. 18, Numbers xix. Similar rites of purification are common to pagan religions whether of ancient or modern times. In the ritual of the Roman Catholic Church, the rinsing of the chalice after communion and the ablution of the fingers of the celebrant after the same are called a purification.

Purification of the Blessed Virgin Mary, Feast of the, a festival observed in the Roman Catholic Church on 2 February: in the calendar of the Episcopal Church in the United States as well as in that of the Established Church of England the Purification of the Virgin Mary is entered for the same day, and in the Book of Common Prayer there are collect and lessons for the day of "the Presentation of Christ in the Temple, commonly called the Purification of Saint Mary the Virgin." The events commemorated by the Church on this day are those recorded in the gospel of St. Luke, ii. 22-39, namely, the go-

PURIFYING APPARATUS — PURITANISM

ing of the Virgin to the Temple 40 days after the birth of her son, for her ritual purification after childbirth, according to the prescriptions of Leviticus xii.; the presentation of the babe to the Lord; and the prophecies of Simeon and Anna. The Christian festival of the Purification was solemnized by the Church at least as early as the end of the 6th century. It is customary on this day, in Catholic countries, for the people and clergy to form processions, each one carrying a lighted candle, signifying the light which the Redeemer brought into the world.

Purifying Apparatus (Electrolytic), for purifying liquids, especially water, for industrial, city and town purposes; a recent invention is an improved apparatus and system for the purification of sewerage and water supply. After several years' experimenting with various metals for an electrode to coagulate the impurities in water (organic and inorganic) it has been found that certain metals are capable of producing while under the action of an electric current immersed in the liquid to be purified, in the form of a sheet or plate, an insoluble hydroxide of the chlorides and sulphates held in solution, which are set free by the action of current passing through the liquid (see **ELECTROLYSIS**); hydrogen being evolved at the cathode and oxygen at the anode, which destroys the animal and vegetable life, leaving the water clear, free from odor and disease-breeding germs, sparkling, with a pure water taste (see **DISTILLATION**). For municipal supply, means are provided for the generation of electricity by either hydraulic or artificial power, using large basins for the water to flow through containing the electrodes, which purifies on its passage out of the basin into a coagulating section, being provided with means to retard the suspended matter, allowing the water to flow down an inclined weir for the purpose of aeration, into another compartment of the basin containing screens, which clarifies it free from all sediment, thence to storage reservoirs; occupying small space as compared to sand bed filters and automatic in operation. The apparatus for potable and industrial use consists of vessels capable of working under high pressure as for boiler feed purposes, one of which contains the electrodes or a series of them for very large supply; the electrodes being connected to a suitable source of electric supply, the vessels being provided with air-valves and insulators to prevent the grounding of the current, and connected to other vessels by suitable conduits to remove the suspended matter, thus permitting a constant flow of the water through the apparatus, requiring small space and installed at any convenient point that the water can be conveyed to. A special feature of the device is the means employed to reduce the consumption of the electric current which has been one of the chief sources why heretofore this method of purifying liquids by electrolysis has not been commercial. The theory of using electricity to purify liquids has long been known from a laboratory standpoint, but the methods and electrode used by this company have established the practical and commercial value of this system for the purification of liquids by electrolysis, on a large scale.

WILLIAM R. CHIPMAN,

Chief Engineer Chipman Electric Purifying Company of New York.

Purim, *poo'rim*, the Festival of Lots, which was instituted by Mordecai (Esther ix. 27-x. 3), and is celebrated to this day by the Jews on the 14th and 15th of the month Adar (March), in commemoration of their wonderful deliverance from the destruction with which they were threatened by Haman. On these festive days the book of Esther is read, presents are interchanged, and gifts are sent to the poor. The great popularity of this festival in the days of Christ may be gathered from the following remark of Josephus: "Even now all the Jews that are in the habitable earth keep these days as festivals and send portions to one another." It is supposed that it was this feast which Jesus went up to celebrate at Jerusalem (John v. 1). It is universally celebrated by the large Hebrew population in the United States.

Puritan City, a name applied to Boston, Mass., referring both to the early settlers and the characteristics of its modern inhabitants.

Puritanism. The Puritans were those who thought that the English Reformation had not gone far enough in its separation from the Roman Catholic Church, but that there were many ceremonies and forms still retained in the worship which were too suggestive of Papacy. They held that it was not expedient or right to retain the use of the cross in baptism, the clerical vestments, the custom of kneeling at the altar, and other forms which had been rejected by the Reformed Churches on the Continent. They believed that the worship should in this way be purified and that only those who lived upright lives should be the ministers of the church. To them the church was a means of advancing religious truth, and it could not do this to the best advantage while hampered, as they thought, by useless, misleading and unscriptural forms and ceremonies, especially when these forms and ceremonies were obligatory for all and the observance of them enforced by the civil authority. During the persecution of the Protestants in the reign of Mary, hundreds of the English reformers went to the Continent and were in the company of the leaders of the Reformed Church. When Elizabeth came to the throne, these men returned and became the leaders of English protestantism. Some of them regarded the wearing of the vestments prescribed by the Church authorities as a matter of indifference, others refused to wear them. They did not object to the government of the Church of England or the close connection between Church and State or the doctrinal system, but objected to what they regarded as the remnants of popery.

Whether they would be allowed to do as they wished or not depended largely on the attitude of the queen. Elizabeth was a woman whose religious tastes were stronger than her religious convictions and the simplicity and bareness of the worship of the Reformed Church offended her. She disliked Puritanism because the teachings of men like John Knox opposed her idea of the royal power. She opposed any puritanical modifications of the Prayer Book or of the ceremonies of the church. That there was to be no room for nonconformity was shown when her first parliament passed the Act of Uniformity, which made unlawful any form of public worship but that of the Prayer Book, and the

Act of Supremacy, by which the queen was acknowledged supreme governor of the realm in spiritual and ecclesiastical affairs. She resolved to retain in the worship as much show and form as possible, and ordered uniformity in vestments. If any refused they were forbidden to preach and deprived of their office. This law was not strictly enforced at first, but with greater rigor as the time went on. Large numbers were ejected from their churches, but continued to hold private meetings. Many were imprisoned and treated with severity. But nonconformity continued to grow notwithstanding the efforts to suppress it.

In early Puritanism the objection is mainly to the forms and ceremonies in the worship of the church. In the later years of the reign of Elizabeth, attention is given to the government of the Church and the relation between Church and State. Elizabeth claimed that in this her will was supreme. Some of the Puritans, above all others, Thomas Cartwright, taught that the only right form of Church government was that laid down in the New Testament and that it was Presbyterianism. He taught that the civil authorities are not to interfere in Church affairs, but they are bound to protect it. There is still to be a state church but with a Presbyterian rather than an Episcopal form of government. This was directly opposed to the Queen's supremacy, and her efforts to suppress this form of Puritanism were vigorous. These Puritan movements were within the Established Church, but there were some who believed that a church having any connection with the state was unscriptural and so there arose the party called Independents or Separatists. They taught that the local church was independent and should manage its own affairs. These were also called Brownists from Robert Browne, who was their first leader. The Separatists were severely persecuted and many left the country. Thus, at the close of the reign of Elizabeth, there are three kinds of Puritans: those who desire a purified worship and still remain in the Church, those who would have a state church under the Presbyterian form of government, and those who believed that an established church was wrong. Hopes were entertained that James VI., educated in Presbyterian Scotland, would be more favorable to Puritanism. The clergy petitioned him for freedom from the burden of human rites and ceremonies and the matter was considered at the Hampton Court Conference. But James' motto was "No bishop, no king," so they could look for little toleration. Uniformity was enforced with great vigor and many Puritans deprived of all hopes of redress left the country. This condition continued with even greater severity in the reign of his son, Charles I., and there seemed in the early part of his reign no check on his tyranny in church and state. Despairing of freedom in Old England, Puritan and Separatist turned to America to create there a New England. In 1620 a little company of Separatists after a sojourn in Holland came to America and settled at Plymouth. In the course of the next 20 years thousands of Puritans settle in Massachusetts. This Puritan emigration stops in 1640, when there seems a better prospect of liberty in England. The Puritan emigrants came as members of the Church of England with no desire to separate. The Pilgrims were already

separated from the English communion and were independent in their church government. But the Puritans because of their distance from the home country and because of the influence of the Pilgrims very quickly adopted the Congregational or Independent form of church government.

Pu'ritans. See PURITANISM.

Pur'kinge's Figures, in optics, figures produced on a wall of uniform color when a person entering a dark room with a candle moves it up and down approximately on a level with the eyes. From the eye near the candle an image of the retinal vessels will appear projected on the wall.

Purple of Cassius, a purple substance used to some extent in the arts, discovered by Dr. Cassius at Leyden in 1683. This substance is probably an oxide of gold containing small quantities of oxide of tin; it is prepared by adding protochloride of tin, along with a little perchloride, to a solution of chloride of gold, when it is thrown down in the form of a dark purple-colored precipitate. Purple of Cassius, mixed with borax and applied to the surface of china, imparts a beautiful rose-pink or rich purple color, according to the quantity employed.

Purple Color. The ancients attributed the discovery of purple to the Phœnicians. The story of its having been discovered by a dog biting a purple-fish, and thus staining his mouth, is well known. The purple-fish was found not only on the Phœnician coasts, but in all other parts of the Mediterranean, so that the use of it in dyeing came to be common with other nations. The modern discovery of purple colors from coal-tar makes an important epoch in the history of the dye. Painters in oil and water-colors produce various shades of purple by mixing certain red and blue pigments. For work in oil French ultramarine, often called French blue, is mixed with vermilion or some madder red (madder carmine is best), or one of these reds with cobalt blue if a pale purple is wanted. For permanent purples in water-colors the same blues are used; but one of the madder reds, not vermilion, should be mixed with them. A much richer purple than any of the above mixtures will give is produced by Prussian blue and one of the lakes from cochineal—namely, carmine or crimson lake—but it is not permanent. This purple, as well as that obtained by mixing Indian red with indigo, also fugitive, was much used by water-color painters in past years. Purple madder is the only simple purple pigment available for the artist which is durable, and it is unfortunately costly. All purples are changed to neutral and gray tints by the addition of any yellow pigment. For house-painting maroon lake with a little French blue gives a useful purple. See DYES.

Purple-faced Monkey. See LANGUR; WAN-DEEROO.

Purple Falcon, Order of the. See ORDERS, ROYAL.

PURPLE FINCH — PURUS

Purple Finch, a handsome American finch (*Carpodacus purpureus*) which in some one of its varieties is known throughout the United States and Canada. The male exhibits in spring a plumage beautifully tinged with rose red and crimson; and sings a brilliant melody. These birds nest in orchard trees and similar places, and lay greenish speckled eggs.

Purple Martin, one of the large, lustrous, blue-black swallows of the genus *Progne*, several species of which inhabit South and Central America, while one (*P. subis*) is a familiar visitor in summer to almost all parts of the United States. They originally nested in hollow trees, but in both North and South America have at once associated themselves with mankind as soon as civilization approached their habitat; and now everywhere make their nests about buildings or in garden bird-boxes. They are among the most useful as well as interesting of our insect-hunting birds.

Purple Scale. See SCALE INSECTS.

Purple Shell, a gastropod mollusk of the family *Muricidae* and especially of one section of it of which the genus *Purpura* is typical. A great many species are found in all seas. The true purples form the subfamily *Purpurinae*. The *Muricidae* are carnivorous marine snails very destructive to other mollusks, barnacles, etc. Many of the tropical species of *Murex* and related genera are of large size and remarkable for the large spines borne upon the shells, but our representatives of the family are small and inconspicuous. (See DRILL.) Our true purple shell (*Purpura lapillus*) is found in great abundance on rocky coasts on both sides of the North Atlantic, but is infrequent in the United States south of Long Island Sound, where it is replaced to some extent by related species. The shell is very thick and solid, short oval with a low spire and a large aperture, the outer lip of which is marked with revolving ridges. It is extremely variable in size, shape, color, and markings. Like the drill it is carnivorous, but with us confines its attacks chiefly to the barnacles which encrust the rocks between tides, though in Europe it works great havoc on the mussel beds.

The name "purple shell" applied to this group of mollusks is derived from the use to which certain species were put by the ancients in the preparation of their most valued dye-stuffs, for which the city of Tyre was especially famous, and upon which its prosperity about 1000 B.C. was founded. The Tyrian purples were of several shades, varying from blue to a dull crimson, dependent upon the particular variety of shell employed and the substances mixed with the extract. Among the most important species utilized were *Murex trunculus*, *M. brandaris*, and *Purpurea patula*. These snails were gathered on both the African and European shores of the Mediterranean. The smaller ones were crushed in mortar-shaped holes in the rocks and mixed with soda, urine, sea-water, and other substances; the larger animals were removed from their shells or the dye squeezed out. The desired colors were obtained by exposure to the sun and by various combinations, and the cloth was steeped in a large excess of fluid until the proper effect had been produced. The fluid is contained in a saccular gland which opens into

the mantle cavity and has at first the color and consistency of cream and a disagreeable odor, but changes to purple upon exposure to light. Consult Simmonds, 'Commercial Products of the Sea.'

Pur'pura. See PURPLE-SHELL.

Purse, a specific sum of money, usually awarded as a prize in athletics, horse-racing, and other sports. In Turkey it consists of 500 Turkish piastres, and its value is \$22; in Egypt a purse consists of 500 tariff piastres, value \$25; in Persia, 50 tomans, value \$107. See PRIZE.

Purser, a name applied to the cashier or chief clerk on board a passenger steamer. In the navy a purser was formerly an officer who took charge of the provisions of a ship of war, and saw to their distribution among the officers and crew. He had very little to do with money matters, but generally bore an evil reputation among the sailors for unfair dealing and rapacity. The designation is now discarded for that of paymaster, who holds a different position.

Purs'lane, a pot-herb and well-known weed forming good fodder for pigs and called "pussley" by farm-hands. See PORTULACA.

Pursuivant, pèr'swī-vant, a title used in the heraldry of England, Scotland, and Ireland, and derived from the Latin word "prosequi," to follow. It is the lowest of heraldic offices, but from the pursuivants were usually selected the superior officials known as herald and king-at-arms. The English college of arms has four pursuivants, the Scottish heraldic establishment has three, and the Ulster king-at-arms in Ireland has four.

Puru-Purus, poo-roo'-poo-roos', or **Puru Pulas**, a tribe of Brazilian Indians, now extinct or represented only by the Pamary or Pamyary, but formerly living along the Purus River (q.v.) in western Brazil. They were naked savages, who slept on the sand instead of in hammocks, and were afflicted by a leprous disease which covered them with bluish and whitish spots. They used practically no sheltering or covering, except leaf umbrellas, and wore their hair long and unkempt, cut only on the forehead in a square bang. Linguistically they seem to have been separate from the surrounding peoples.

Puruandiro, poo-roo-än-dē'rō, Mexico, a town of the state of Michoacán and capital city of the district of Puruandiro in central Mexico, situated on the southern shore of a small lake, about 42 miles northwest of Morelia. It does a small business in Mexican leather and in the agricultural produce of the surrounding country. Pop. (1895) 7,782.

Purus, poo-roos', a South American river, an affluent of the Amazon, rising in the east of Peru traversing the northwest corner of Bolivia, entering Brazil, and after a northeastward course of over 1,800 miles, joining the Amazon about 100 miles above the latter's confluence with the Madeira. It has a very winding course and a comparatively slight fall. In the flood season it is navigable almost throughout its length. Chief among its numerous tributaries is the Acre. Its source was discovered in 1864 by Chandless, an English explorer.

Purver, pèr'vèr, **Anthony**, English translator: b. Hurstbourne, Hampshire, 1702; d. Andover, Hampshire, July 1777. He was at first apprenticed to a shoemaker, but mastered Hebrew, and at 20 opened a school. Later he went to London where he became a Quaker and there began his translation of the Bible in 1733, a task which occupied him for 20 years. It was completed in 1763 and published under the title 'A New and Literal Translation of all the Books of the Old and New Testament' (1764). The publication was known as the 'Quaker's Bible' and by many was pronounced crude and unscholarly, while warmly approved by Southey and other critics. He also published: 'Youth's Delight' (1727); 'Poem to the Praise of God' (1748); and 'Counsel to the Friend's Children' (1785).

Purves, pèr'vès, **George Tybout**, American clergyman: b. Philadelphia, Pa., 27 Sept. 1852; d. New York 24 Sept. 1901. He was graduated from the University of Pennsylvania in 1872 and from the Princeton Theological Seminary in 1876. He was pastor at Wayne, Pa., 1877-80; and professor of New Testament literature and exegesis at Princeton Theological Seminary 1892-1900. In the last named year he accepted a call to the 5th Avenue Presbyterian Church, New York. He wrote: 'The Testimony of Justin Martyr to Early Christianity'; 'The Apostolic Age'; etc.

Purvey, pèr'vī, **John**, English Biblical translator: b. Lathbury, Buckinghamshire, about 1354; d. about 1427. While associated with Wyclif, whose disciple he became, he undertook with other scholars the revision of the translation of the Bible made by Wyclif in 1380. The revision was substantially a new work merely based on Wyclif's copy which had retained many Latinisms from the Vulgate. The new translation, on the other hand, was made in good idiomatic English. It was completed about 1388, four years after Wyclif's death. For his Wyclifite views he was imprisoned in 1390, recanted to escape martyrdom in 1401, and for two years was vicar of West Hythe, Kent. Purvey wrote against the corruption of the Church, a work entitled 'Ecclesiæ Regimen.' Consult: Lechler, 'John Wiclif and his English Precursors,' translated by Lorimer (1884).

Pus. See SUPPURATION.

Pusey, pū'zī, **Caleb**, American Quaker colonist: b. Berkshire, England, about 1650; d. Chester County, Pa., 25 Feb. 1727. He was educated a Baptist, but joined the Quakers and came with Penn's company to America in 1682, erected the first mills in the province known as the "Chester Mills," and of which Penn himself laid the cornerstone. He laid out roads, treated with the Indians, was sheriff of Chester County for two years, justice of the peace and of the county courts for many years, an associate justice of the supreme court, and for 10 years member of assembly. He published a great number of pamphlets and articles in defense of his creed, among them: 'A Serious and Seasonable Warning' (1675); 'A Modest Account from Pennsylvania of the Principal Differences in Point of Doctrine between George Keith and those of the People called Quakers' (1696); 'Satan's Harbingers Encountered' (1700); etc.

Pusey, Edward Bouverie, English scholar and theologian: b. near Oxford 22 Aug. 1800; d. Ascot Priory, Berkshire, 16 Sept. 1882. He was a son of the Hon. Philip Bouverie (of the Radnor family), who assumed the name of Pusey by royal license on becoming lord of the manor of that name in Berkshire. He was educated at Eton and Oxford University, where he was graduated with first class honors. Soon after he was elected to a fellowship at Oriel College. He studied for two years in Germany, taking up more especially Oriental languages, theology, and German, and in 1828 was appointed regius professor of Hebrew, a post which he retained all his life, and to which a canonry at Christ Church is attached. In 1826 he had published a book summarizing the progress of German theological thought since the Reformation, expounding the rationalistic views regarding religion which were common in Germany, his account of which was founded on his own personal experience of what he believed to be the evils of Rationalism. He became through the influence of his friends Hurrel, Froude, and Newman an ally of the theological party who started the Tracts for the Times (see TRACTARIANISM), but the agitation had been going on a little time before he took an active part in it. His first tract was the 18th, 'On the Benefit of Fasting'; he subsequently wrote another (the 66th) on the same subject, and two (the 67th, and 69th) 'On Holy Baptism.' In connection with the same High Church movement he undertook the joint-editorship of the 'Library of the Fathers' and the 'Library of Anglo-Catholic Theology.' In 1843 he was suspended from preaching in the university pulpit for three years on account of a sermon on the Eucharist, in which he advocated the doctrines of the real presence, sacerdotal absolution, and of the duty and privilege of confession. Except for literary labors and occasional sermons, Dr. Pusey's life was henceforward an uneventful one. Among his chief works are a treatise on 'The Ancient Doctrine of the Real Presence'; 'Letters to the Archbishop of Canterbury in Defence of Church Principles'; a treatise on 'Marriage with a Deceased Wife's Sister'; a 'History of the Councils of the Church' (1857); a learned 'Commentary on the Minor Prophets' (1860-77), an important contribution to Hebrew scholarship. Nine lectures on 'Daniel the Prophet' (1864), and 'The Church of England, or Portion of Christ's Holy Catholic Church: an Eirenicon' (1865). As a leader of the Tractarian or High Church party he kept a large section of that party from drifting into the Catholic Church and remained unshaken in his fidelity to the church of his baptism, while Oakley, Ward, Wingfield, Newman, and more than 100 other English clergymen went over to Rome. On this ground, perhaps, the party received the popular name of Puseyites. Pusey was one of the few Oxford professors whose linguistic accomplishment laid open to him the latest researches and discoveries of German scholarship. He was very retired in his habits, but kind-hearted, and his charity was unbounded. Pusey House, one of the most recent of Oxford colleges, was founded as a memorial to him, and was intended to continue the tradition of his teaching which it has done to the same extent as All Souls has fulfilled the purpose of offer-

ing masses for the repose of the souls of those who perished in the Hundred Years' war. Consult: Liddon, 'Life of Edward Bouverie Pusey' (1893-7); Grafton, 'Pusey and the Church Revival' (1902).

Puseyism. See OXFORD MOVEMENT, THE.

Pushkin, poosh'kin, Alexander (spelled also **POUSHKIN, POUCHAKIN**), Russian poet: b. Moscow 26 May (7 June) 1799; d. Saint Petersburg 29 Jan. (10 Feb.) 1837. He received his first education in the Lyceum at Tsarskoë-Selo. In 1817 he entered the service of the government in the ministry of foreign affairs, in 1820 was retired to southern Russia because of his liberal opinions, until 1824 was a subordinate in the office of the governor-general of Odessa, angered his superior by an epigram, and was withdrawn wholly from the service and ordered to live on his estate of Mikhailovskoë. In 1826 Nicholas I. allowed his return to Saint Petersburg, where he was made imperial historiographer. His only work of research, however, was the 'History of the Revolt of Pugachev'; he labored in the archives on an account of Peter the Great, which came to nothing. He died from a wound received in a duel, and the Czar appropriated 150,000 rubles to settle his affairs and publish his works. These included, above all, 'Evgenie Onyegin' (1828), a metrical narrative in a somewhat Byronic fashion; and 'Boris Godunov,' a tragedy dealing with the troublous period following the death of Czar Feodor. Pushkin performed a great service for the Russian language and literature; molding the former, which, prior to his time was uncouth and unwieldy, and freeing the latter from its French tradition and placing it solidly upon a native basis. He has been called "undeniably and essentially the great national poet of Russia." There are English renderings of 'Evgenie Onyegin' (by Spalding, 1881); of the 'Poems' (by Panin, 2d ed. 1888); and of the 'Prose Tales' (by Keane, 1896). A memorial work, 'Translations from Pushkin,' by Turner, appeared in 1899. Consult: Shaw, 'Sketch of Pushkin's Life and Works' (1845); Flach, 'Un Grand Poète Russe' (1894).

Puss in Boots, a well-known nursery tale by Charles Perrault, whose version, 'Le chat botté' appeared in his 'Contes de Fées' (1697). It was probably taken from Straparola's 'Piacevoli Notti.' The story is found in a Norse version in 'Lord Peter,' and in the Swedish 'Palace with Pillars of Gold,' in which the cat befriends a girl, whose adventures are similar to those of the Marquis of Carabas. In a Sicilian version is found the first hint of a moral which is lacking in the above-mentioned tales; that is, the ingratitude of the man. Cosguin imagined from the moral that its origin was Buddhist, for the story could only have arisen in a comparatively civilized community; but the only Hindu version, the 'Match-Making Jackal,' discovered about 1884 in Bengal, has no moral at all. The most complete moral is found in Zanzibar, in the Swahili tale of 'Sultan Darai,' in which the beneficent beast is a gazelle: the ingratitude of the man is punished by the loss of all that he had gained; the gazelle, which dies of neglect, is honored by a public funeral. A well-known German version is that by Tieck, 'Der gestiefelt Kater' (1795).

Pustules. See PIMPLES.

Put Yourself in His Place, a novel by Charles Reade, published in 1870. The scene is laid in an English manufacturing town, and the story narrates the struggles of Henry Little, workman and inventor, against the jealousy and prejudice of the trades-unions. Like all of Reade's stories, 'Put Yourself in His Place' has a wealth of dramatic incident, and moves with dash and vigor.

Putchock, pū-chōk', or Puchuck, the root of *Aplotaxis lappa*, the "costus" of the ancients, a composite plant growing on the Himalayas in the vicinity of Cashmere. It has long lyrate leaves and heads of purple florets. It is exported to the Malay countries and to China, where it forms a main ingredient in the Chinese pastille-rods known as joss-sticks. In Upper India it is given as a medicine in various complaints ranging from coughs to cholera, and is also employed in several other ways.

Putlitz, poot'lits, Gustav Heinrich Gans, EDLER HERR VON UND ZU, German novelist and poet: b. Retzin, Prussia, 20 March 1821; d. there 9 Sept. 1890. He was educated at Magdeburg, Berlin, and Heidelberg, was engaged in the civil service in 1846-8 and made his début in literary circles by his comedies which aptly portrayed high social life and excelled in humor. In 1863 he was appointed director of the court theatre at Schwerin, and his collected dramas were published in 1850-69. His poems were characterized by much beauty and grace and his charming fairy poem 'Was sich der Wald erzählt' (1850) was widely circulated. His novels were also popular. Among his publications are: 'Vergissmeinnicht' (1851); 'Brandenburger Geschichten' (1862); 'Novellen' (1863); 'Funken unter der Asche' (1871).

Putnam, pūt'nām, Frederick Ward, American archaeologist and ethnologist: b. Salem, Mass., 16 April 1839. He became curator at Essex Institute in Salem in 1856, was graduated from Harvard in 1862, and in 1864 became director of the Essex Institute museum. In 1867 he was appointed superintendent of the East Indian Marine Society's museum at Salem and in 1875 was appointed civilian assistant on the United States surveys west of the rooth meridian, his duties being to make investigations and reports of the archaeological and ethnological material collected. In 1876-8 he was in charge of the Agassiz collection of fishes at the Museum of Comparative Zoology and in 1886 was appointed professor of American archaeology and ethnology at Harvard. He was chief of the department of ethnology at the World's Columbian Exposition in 1893. He is author of numerous pamphlets on scientific subjects, was one of the founders and editors of the 'American Naturalist,' and has edited many volumes of 'Annual Reports of the Trustees of the Peabody Museum of Archaeology and Ethnology' and 'Proceedings of the Essex Institute.'

Putnam, George Haven, American publisher and author, son of G. P. Putnam (q.v.): b. London, England, 2 April 1844. He was educated in New York, Paris, and Göttingen, leaving the university at the latter place to enter the Union army as a volunteer in 1862. He served through the war, was a prisoner at Libby in the winter of 1864-5, and attained rank as major of volunteers. He is head of the firm

G. P. Putnam's Sons, was a leader in reorganizing the American Copyright League in 1887, and was instrumental in securing the passage of the copyright bill in 1891. He has published: 'Authors and Publishers' (1883); 'The Artificial Mother' (1894); 'Books and their Makers in the Middle Ages' (1896); etc.

Putnam, George Palmer, American publisher and author: b. Brunswick, Maine, 7 Feb. 1814; d. New York 20 Dec. 1872. He entered the book store of Jonathan Leavitt in New York in 1828, became a member in the firm Wiley and Putnam in 1840 and in 1841 went to London where he conducted a branch business. In 1848 he returned to New York, opened a publishing house, engaged in the production of finely illustrated books and established 'Putnam's Magazine' 1853-6, which was resumed in 1868 and afterward merged with 'Scribner's Monthly.' In 1866 he established the publishing firm now known as G. P. Putnam's Sons. He was an ardent advocate of international copyright reform, secretary for many years of the Publishers' Association, a founder of the Metropolitan Museum of Art, and wrote: 'A Plea for International Copyright' (1837); 'Chronology' (1833); 'The Tourist in Europe' (1838); 'American Facts' (1845); 'The World's Progress' (1850); 'Ten Years of the World's Progress' (1861); etc.

Putnam, Herbert, American librarian: b. New York 20 Sept. 1861. He was graduated from Harvard in 1883, studied law at Columbia and in 1886 was admitted to the bar. He was librarian at the Minneapolis Athenæum in 1884-7 and of the Minneapolis Public Library 1887-91; practised law in Boston in 1892-5, was librarian of the Boston Public Library in 1895-9 and in the latter year was appointed librarian of Congress. He became president of the American Library Association in 1898 and one of the overseers of Harvard in 1902.

Putnam, Israel, American Revolutionary soldier: b. Salem (now Danvers), Mass., 7 Jan. 1718; d. Pomfret (now Brooklyn), Conn., 19 May 1790. His education was a desultory one. In 1740 he removed from Salem, and purchased in that part of Pomfret, Conn., which is now Brooklyn, the farm where he afterward resided. It is said that he also hung out a shingle advertising entertainment for man and beast. There is also the well-known anecdote of the exploit in which he crept into the lair of a destructive wolf, and there despatched the animal. But little definite is known of Putnam's life until he is found in 1755 in receipt of a commission as captain of Connecticut volunteers in a regiment sent by the colony to aid in repelling a threatened French invasion of New York. He was present at the defeat of the French and Indians under Dieskau near the southern end of Lake George, and later was very successfully employed as a ranger and scout. In 1756 he commanded a company in Abercrombie's army, which had Crown Point as an objective, but was so outplayed by Montcalm as to be obliged to act rather defensively than offensively. He received a major's commission from the Connecticut legislature in 1757. During Abercrombie's expedition against Ticonderoga in 1758, Putnam commanded an advance guard and scouting party of 100. In the retreat following the rash and disastrous attack on the post, he became aide to

Abercrombie, replacing Howe, who had been shot. Having been sent out in August to recapture from the enemy a large quantity of British stores, he was taken prisoner and tortured by the Indians, but rescued by a French officer. He was sent to Ticonderoga and thence to Montreal, where he was exchanged. Promoted lieutenant-colonel in 1759, he accompanied the force sent against Montreal, upon whose surrender Canada passed into English hands. In 1762 he commanded the contingent of 1,000 sent by Connecticut in the naval expedition against Havana. His vessel was wrecked off the Cuban coast, but those on board escaped by rafts, and took part in the successful attack on Havana. He was sent out against the Indians of the frontier, who, under Pontiac (q.v.), were menacing Detroit, in 1763. A peace was concluded; Putnam returned to his farm, and there remained in retirement until 1775. When the news of Lexington reached him, he is said to have been plowing, Cincinnatus-like; and at once to have turned loose the oxen and ridden to Cambridge. A Connecticut regiment was forthwith organized, and Putnam, with a brigadier's commission, appointed to command it. In May he led a battalion to Noddle's Island, where he captured a sloop and burned a schooner of the enemy. He was a participant in the battle at Breed's (Bunker) Hill, which he had helped to fortify; the chief command in the action has been claimed for him against Prescott. Trumbull, in his picture in the Capitol at Washington, shows Putnam in brilliant uniform defending a gun. Commissioned major-general in July, he was placed in command at New York, and was ranking officer within the fortifications during the battle of Long Island. After having been stationed at Philadelphia, Crosswick, and Princeton, he was sent in May 1777 to command in the "Highlands" of New York. Owing to the loss of Fort Montgomery and Fort Clinton, he was removed from his command; but later was restored on being acquitted by a court of inquiry. Subsequently, when he was commanding in Connecticut, Horseneck, an American outpost, was attacked by the British under Tryon. Putnam, according to the story, escaped by dashing on horseback down-hill, and eventually pursued the retreating Tryon, from whom he took 50 prisoners. In the winter of 1779 he was stricken with paralysis and incapacitated from further service. Consult 'Lives,' by Tarbox (1876) and Livingston (1901).

Putnam, John Pickering, American architect: b. Boston, Mass., 1847. He was graduated from Harvard in 1868, studied later in the Ecole des Beaux Arts, Paris, and in the Royal Academy of Architecture, Berlin. He has since practised his profession in Boston and has published: 'The Open Fire Place in All Ages'; 'The Principles of House Drainage'; 'Improved Plumbing Appliances'; 'The Outlook for the Artisan and His Art.'

Putnam, Mary Traill Spence Lowell, American author, sister of James Russell Lowell (q.v.): b. Boston, Mass., 3 Dec. 1810; d. there 1 June 1898. She was married to Samuel R. Putnam in 1832, and later traveled abroad for several years. Her literary work was confined to magazine writing until 1844, when she translated from the Swedish Fredrika Bremer's 'The Handmaid.' She afterward published: 'His-

PUTNAM — PUTTENHAM

tory of the Constitution of Hungary' (1850); 'Records of an Obscure Man' (1861); 'The Tragedy of Errors' and 'The Tragedy of Success,' a dramatic poem in two parts (1862); 'Fifteen Days' (1866); 'Memoir of Charles Lowell' (1885); etc.

Putnam, Rufus, American Revolutionary soldier: b. Sutton, Mass., 9 April 1738; d. Marietta, Ohio, 1 May 1824. He was apprenticed in 1754 to a millwright, but acquired some knowledge of surveying and later found employment in that profession. In March 1757 he enlisted as a private for service in the French and Indian war; and re-enlisted yearly until 1761, being made ensign in 1760. His story of the campaigns in which he served may be read in the 'Journal' which he kept throughout. He was a farmer successively at New Braintree, Mass. (1761), Brookfield, Mass. (1765), and Rutland, Mass. (1780). In 1773 he went to Florida as one of an investigating committee appointed to examine lands granted by the crown to colonial soldiers and officers who had fought in provincial regiments during the French and Indian war. Putnam was made deputy-surveyor of Florida by the governor of the province, and accompanied the expedition up the Mississippi to the Yazoo, up the Yazoo to Haines' Bluff, back to the Big Black, and thence in return down the Mississippi. He planned and directed the construction of the Continental lines of defense at Roxbury, and for the excellence of his work was detailed by Washington as acting chief-engineer of the army. On 11 Aug. 1776 he was appointed by Congress chief engineer of the army, with colonel's rank; but preferring service in the field, he resigned in December and took command of the 5th Massachusetts regiment. With the northern army in 1777 he did conspicuous service, particularly at Stillwater, where he headed the 4th and 5th regiments of Nixon's brigade. On 7 Jan. 1783 he was promoted brigadier-general. He was for several years a member of the Massachusetts legislature, and during Shays' rebellion (q.v.) (1786-7) was a very efficient aide on the staff of Gen. Benjamin Lincoln. In March 1787 he was chosen (with Gen. S. H. Parsons and Rev. Manasseh Cutler) a director of the Ohio company, organized (1 March 1786) with a capital of \$1,000,000 in public securities, to be expended in the purchase of land in the Northwest Territory. In July a contract was made with Congress for one and a half million of acres, and soon afterward an ordinance, familiarly known as the "Ordinance of 1787," was passed providing for the government of the territory. On 7 April 1788 Putnam, meanwhile made superintendent of the company, landed with a party of emigrants at the mouth of the Muskingum, and on the present site of Marietta commenced the first organized settlement in the Northwest Territory. He concluded in 1792 at Vincennes a treaty with eight tribes of the Wabash Indians, and in 1793 resigned his commission in the army. He was one of the judges of the United States court in the Territory, 1790-6, and from 1796 until his removal by Jefferson for political reasons in 1803 was surveyor-general of the United States. He was the founder of the first Bible society west of the Alleghanies (1812), a sturdy Federalist in politics, and with the exception of Lafayette the last survivor of the

general officers of the Continental army. Consult his 'Journal,' edited, with sketch, by Dawes (1886). Putnam's papers, including the manuscript 'Journal' and correspondence with Fisher Ames, Trumbull, Washington, and others are preserved at Marietta in the library of the college there; they were edited by Rowena Buell (1904) under the title 'The Memoirs of Rufus Putnam and Certain Official Papers and Correspondence.'

Putnam, Sarah A. Brock, American writer: b. Madison Court House, Va., about 1845. In 1883 she was married to the Rev. Richard Putnam, an Episcopal clergyman. She has published: 'Richmond during the War' (1867); 'The Southern Amaranth' (1869); 'Kenneth, My King' (1872); 'Myra,' a novel.

Putnam, William Le Baron, American jurist: b. Bath, Maine, 12 May 1835. He was graduated from Bowdoin College in 1855, admitted to the bar in 1858 and engaged in law practice in Portland, Maine, 1858-92. In 1887 he accepted an appointment by President Cleveland as commissioner to settle with Great Britain the rights of American fishermen in Canadian waters, and was also a member of the commission under the treaty of 6 Feb. 1896 between Great Britain and the United States. He had twice declined appointments as justice of the Maine supreme judicial court, but in 1892 accepted an appointment as judge of the United States Circuit Court. In 1888 he was the Democratic candidate for the governorship of his State.

Putnam, Conn., city, one of the county-seats of Windham County; on the Quinebaug River, and on the Norwich & W. and the New York, N. H. & H. R.R.'s; about 45 miles east by north of Hartford. It was incorporated from portions of the towns of Thompson, Killingly, and Pomfret, by the State Assembly in May 1855, and was organized as a municipality 3 July 1855 and in 1895 was chartered as a city. Nearby are Cargill Falls, noted for their beauty. It is in an agricultural region, but it has a number of manufacturing interests. The chief industrial establishments are cotton and woolen mills, boot and shoe factories, silk mills, and manufactories of heaters and castings. The number of employees in the manufactories is about 1,900. It has the Day Kimball Hospital, Saint Mary's Convent, and seven churches. The educational institutions are Notre Dame Academy, a high school, public and parish schools, and a public library. There are two banks, one National, with a capital of \$150,000, and one savings, and the business annually is over \$20,000,000. The government is administrated under the charter of 1895 which provides for a mayor, who holds office two years, and a council of nine members. Pop. (1900) 6,667.

Putnam, Fort, a former Revolutionary fort at West Point, N. Y.

Puts and Calls. See STOCK EXCHANGE.

Puttenham, püt'en-am, **George**, English author: b. about 1530; d. about 1600. He is reputed to be the writer of a work entitled 'The Arte of English Poesie, contrived into three bookes; the first of Poets and Poesie, the second of Proportion, the third of Ornament,' which appeared anonymously in 1589. The Arte is a review of ancient as well as modern poetry, and was written for the court. It shows consid-

erable literary knowledge and no small critical power. Its author wrote several other pieces which have been lost. The authorship of 'The Arte' has also been claimed for Richard Puttenham, his brother.

Puttiala, püt-të-ä'lä. See PATIALA.

Puttkamer, poot'kă-mër, **Robert Viktor von**, Prussian statesman: b. Frankfort-on-the-Oder 1828; d. Karzin, Prussia, 15 March 1900. He was educated at Heidelberg, Geneva, and Berlin, entered government service in 1854, and as a friend and relative of Bismarck his rise was rapid. He was elected to the Reichstag in 1873 as a Conservative member and in 1877 was chief president of the province of Silesia. In 1879 he became minister of education and public worship and endeavored to carry out the compact Bismarck had made with the Clericals. In 1881 he was appointed minister of the interior and vice-president of the ministry. He energetically enforced measures against the Socialist party and his methods in favoring the election of government candidates aroused the opposition of the Radicals and were bitterly attacked in a speech by Eugen Richter. After the accession of Friedrich III., Puttkamer resigned, and though it was expected that he would be reinstated when Wilhelm II. came to the throne, he was merely appointed chief president of Pomerania in 1891.

Put'tun. See PATTAN.

Putty, a substance compounded of whiting and linseed-oil, beaten together to the consistence of a thick dough. It is used by glaziers for the purpose of fixing sheets of glass in the frames of windows, etc., and also by painters for filling up holes in the surface they are about to paint. It becomes very hard when dried.

Putumayo, poo-too-mă'yō, or **Iça**, a South American river, rising in the southwestern part of Colombia on the eastern slope of the Cordillera. It flows southeast for about 1,000 miles, almost on the line of the equator in its mid-course, receives at the right the San Miguel and the Yahuas, and at San Antonio after about 150 miles in Brazil empties into the Amazon. It was explored by Reyes and Crevaux, is navigable within 100 miles of its source, and promises to be a valuable commercial waterway between Brazil and Colombia.

Puvis de Chavannes, **Pierre**, pē-är pū-vēs dē shā-văn, French painter: b. Lyons 14 Dec. 1824; d. Paris 25 Oct. 1898. He sprang from an old Burgundian family of strong Catholic traditions. His father was an engineer and he himself was destined to the same career, but an intervening illness and a journey to Italy confirmed a predilection for painting. His first master was Ary Scheffer, with whom he studied but a short time, and went for a second visit to Italy. Returning he put himself under the tuition first of Delacroix, then of Couture, but parted from each of them after a short period, as he had with his former master, from an inability to submit to any leading but his own artistic instincts. Certain marks of the influence of these men are seen by critics, particularly of Delacroix, even in the very latest products of Puvis' life. These may be traced in the more fundamental traits of his drawing, in the composition, spacing and the like. Others incline

to the belief that his work rather suggests the influence of his early visits to Italy, in a sort of reminiscence of the frescoes of Piero della Francesca. Such suggestions seem for the most part only an effort toward discovering subtle resemblances urged on by the really insistent originality of this artist's work. Working out his own theories which were at variance with all the ruling traditions of his day it is not wonderful that he should have encountered opposition. The Salon refused his work nine times. In 1861 came his first recognition when he gained a second-class medal and sold his pictures 'War' and 'Peace' to the state. These were placed in the Museum of Amiens to which the painter later presented the companion pieces 'Rest' and 'Labor.'

In 1872, as member of the Salon jury, he disagreed with his colleagues and resigned. He was made president of the Society of French Artists, holding their exhibition in the Champs de Mars, and in 1877 was made officer of the Legion of Honor.

As a wall-painter he was the great leader of modern times in recognizing the limitations imposed by this branch of painting and in submitting himself to its demands. He saw that fresco was only the agreeable decoration of a wall surface, which should not attempt to conceal its character as a wall by sharp contrasts of light and shadow and elaborate arrangements of foreshortening and perspective. Consequently he painted in flat tones of cool green, blue, brown or lilac, having always in mind the relation of his designs to their architectural surroundings. His pictures themselves were essentially architectural in their arrangements. Among his mural decorations are those at Marseilles, Lyons, Lille and Poitiers, those in the Hotels de Ville at Rouen and Paris, the Hemicycle of the Sorbonne, in Paris, the series on St. Genevieve in the Pantheon, and the decorations of the staircase of the Public Library in Boston. In the last named work he sought, as he himself stated, "to represent under a symbolic form and in a single view the intellectual treasures collected in this beautiful building. The whole seems to be summed up in the composition entitled 'The Muses of Inspiration hail the Spirit, the Harbinger of Light.' Apollo occupies the centre of this panel and the white-robed Muses, draped in filmy white, are ranged in mid-air against a background of pale green grass, with flowering bushes and slender trees, with the deep blue ocean and pale luminous sky stretching beyond. "Out of this composition," writes Puvis de Chavannes, "others have developed which answer to the four great expressions of the human mind, Poetry, Philosophy, History, Science." On the right-hand wall of the staircase as one enters appear in three panels: (1) Pastoral Poetry (Virgil); (2) Dramatic Poetry (Æschylus and the Oceanides); (3) Epic Poetry (Homer crowned by the Iliad and Odyssey).

Puy, Le, lê pū-ē, France, arrondissement and capital city of the department Haute Loire. (1) The arrondissement, a little to the southeast of the centre of the department has an area of 8,680 square miles and a population (1901) of 145,716, and is divided into 14 cantons and 115 communes. Its capital and that of the

department is (2) Le Puy, or Le Puy-en-Velay, lying at the confluence of the Dolezon and the Born, on the sides and top of the Mont Anis (whence its mediæval Latin name of Anicium or Podium Anicense), so that its least elevation is about 2,050 feet above sea-level and its greatest, the volcanic dike called the Rocher de Corneille about 2,500. It is ill-built but picturesque. The Rocher de Corneille is topped by a statue of Notre Dame de France made from Russian cannon taken at Sebastopol. The city is a bishop's seat and has a cathedral at the top of a staircase with 136 steps; other important buildings are an old chapel of the Templars, known as Diana's temple, the Gothic church of St. Michel d'Aiguille (962-984), the splendid marble and bronzé Crozatier Fountain, and the Crozatier Museum, which is especially rich in exhibits of the industries of the town. These are chiefly laces, especially guipure, tulles, woolens, bells and clocks. Pop. (1901) 20,570.

Puy-de-Dôme, pū-ē-dē-dôm, France, a central department of the Auvergne, bounded on the north by Allier, on the east by Loire, on the south by Haute-Loire and Santal, and on the west by Corrèze and Creuse, and so named from the peak 4,086 feet in the Puy-de-Dôme group of volcanic mountains in the northern part of the department. The southern range, called Mont-Dore is higher, and the geology and mountain structure of the region is interesting. The highlands are excellent pastures; rye and oats grow at more moderate elevations; and vineyards, wheat, hemp, and flax-fields cover the lowlands. The forest timber is valuable, as are the mineral waters and the coal deposits. Capital, Clermont-Ferrand (q.v.). Area 3,070 square miles; pop. (1901) 544,194.

Puyallup (poo-yäl'üp) **Indians**, an American tribe, similar to the Nisqually family in Washington and Oregon. They formerly occupied all the region about the Puyallup River. Less than 500 of them were living in 1903 on a reservation near Tacoma.

Puzzola'na. See CEMENT.

Pyæmia (formerly suppurative fever, purulent infection, purulent diathesis, etc.) no longer means pus in the blood, but is a form of blood-poisoning (q.v.) of microbic origin, septic infection due to the absorption of pyogenic germs. The typical pathological condition is the production of multiple abscesses in tissues remote from the seat of injury, produced by living bacteria (forms of cocci probably) transported by the blood. Various experiments have shown that pus taken up by the blood-current does not produce pyæmia unless it contains virulent microbes. Sometimes the abscesses of pyæmia are metastatic or embolic, caused by the lodgment of infected emboli in arterioles or veinlets, the inflammation of these vessels and its extension to surrounding areas. Formerly when antiseptics was unknown it was quite common. At the present time pyæmia is infrequent, except where injuries are much neglected. Yet it may begin in the veins of the face and the sinuses of the cranium, from acute and chronic otitis media, etc. It may be associated with or precede septicæmia (a poisoning due to living bacteria in the blood), and death may result from the general infection of the system. Fortunately absorbed virulent microbes are some-

times killed or neutralized by leucocytes, by the chemical bodies called by Buchner sozins and alexins, by the tissue-cells of the liver, spleen, etc., or may be excreted in a living state by the glandular excretory organs. The onset of pyæmia is marked by depression of the vital powers, chills, fever, sweating, and sometimes jaundice; by a coated dry tongue, a rapid feeble pulse, a foul breath; by constipation, followed by foul-smelling loose movements and by scanty high-colored urine. When these symptoms follow a surgical operation or an injury, and abscesses are not so superficial as to be discovered, deep-seated ones are surmised.

The treatment is preventive and curative. See that the patient's power of resistance is not lowered. Keep the bowels and kidneys active. Intestinal putrefaction must not occur. Sunlight, good air, and nourishing food are necessities. As yet no reliable serum-injection has been found to grant immunity. Wounds should be treated antiseptically, and abscesses be antiseptically opened, cleaned, and drained. Stimulants, quinine, and other tonics are indicated.

Pyat, pē-ä, **Felix**, French journalist and politician: b. Vierzon, France, 4 Oct. 1810; d. Saint Gratien, France, 5 Aug. 1889. He studied law and was admitted to the bar in 1831, but confined his attention chiefly to literature and politics. He was an advocate of the attempted insurrection in 1849, a signer of Ledru-Rollin's appeal to the populace, and was forced to escape from France after the failure of the plan. He busied himself in forming further schemes for revolution, living successively in Switzerland, Belgium and England, and was a member of the "European revolutionary committee." When the general amnesty was granted in 1870 he returned to France, speedily attained leadership among the Paris Communists and was prominent in the destruction of the Vendôme column. The fall of the Commune rendered flight again imperative and for his part in the Communal government he was tried and placed under sentence of death in 1873, though then absent from France. He was pardoned in 1880, returned to France and in 1888 was elected deputy from Marseilles.

Pycnogon'ida. See PANTOPODA.

Pydna, pīd'na, in ancient history, a city of Pieria in Macedonia, originally on the west coast of the Thermaic Gulf, but removed three miles inland by Archelaus. The Athenians controlled it for a time, but lost it to Philip the Great. In 168 B.C. at the battle of Pydna Perseus of Macedonia was utterly defeated by the Romans under Æmilius Paulus, the death-blow of the Macedonian empire. In Byzantine times the city of Kitron or Kitros grew up on the same site, and this name is borne by the present town.

Pye, pī, **Henry James**, English poet-laureate: b. London 10 July 1745; d. Pinner, Hertfordshire, 13 Aug. 1813. He was educated at Oxford and in 1784 entered Parliament from the county of Bucks, but played an unimportant part there. He was crowned laureate in 1790 and dutifully fulfilled the expectations of his office in producing his two odes a year. Other verse came from his pen, but nothing that rises above the dead level of commonplaceness. He was made one of the magistrates of Westminster

in 1792. Pye was a voluminous writer, contributed to the literature of the stage and translated Aristotle's 'Poetics.' He seems, however, not to have set great store on his poetry himself, and observed that he had rather be thought a good Englishman than the best poet or the greatest scholar that ever wrote.

Pye, John, English engraver: b. Birmingham 22 April 1782; d. London 6 Feb. 1874. In 1802 he went to London and came under the influence of John Heath. Success in rendering landscape brought him to the attention of Turner, who engaged him to engrave a plate from his 'Temple of Jupiter at Ægina.' A long Turner series of engravings followed. Being a Turner enthusiast he collected one of the finest sets of plates engraved after that master. He published 'Patronage of British Art' (1845), and began the publication of 'Pictures from the National Gallery,' terminated after 29 parts were issued.

Pygmalion, pîg-mă'li-ôn, (1) in Greek legend a son of Clix and grandson of Agenor, king of Cyprus. In the story told by Ovid (Met. x. 243) he conceived an aversion to women and devoted himself to art, but having made an ivory statue he became so enamored of it that he entreated Aphrodite to endow it with life. This was done; the statue became a beautiful woman whom Pygmalion married and by whom he had Paphos, founder of the city of that name in Cyprus. W. S. Gilbert's play, 'Pygmalion and Galatea,' is founded on this story. (2) Tyrian king and brother of Dido. He murdered Dido's husband Acerbas or Sichæus upon which Dido took her dead husband's treasures and sailed for the coast of Africa where she founded Carthage.

Pygmies, the name given by the ancients to a race of dwarfish men reported as existing in various parts of the world. Homer (Il. iii. 6) fixes the habitat of the pygmies in the far southland whither the cranes migrate at the approach of winter; after Homer the battles of the cranes and the pygmies are a favorite theme of poets, and are often pictured on vases. Ancient authors, whether travelers, historians, or miscellanists, like Herodotus, Ctesias or Pliny, describe the pygmæi as little men, the tallest of them not exceeding in height two *pygmæ* (Gr. *pygme*, a measure of length, the distance from the elbow to the knuckles—less than 14 inches). Herodotus locates his pygmæi in the heart of Africa in a region traversed by a great stream—probably the Niger—flowing from west to east, and modern geographical research gives support to his story after it had long passed for fabulous. In recent times the actual existence of pygmies has been ascertained beyond any question, though when Paul B. Du Chaillu (q.v.) in 1861 published his 'Explorations and Adventures in Equatorial Africa' his description of the pygmy tribes discovered by him was scouted by scientific men as mere fiction. But when his report was confirmed in every essential particular by the missionary Father des Avanchers (1869), by Schweinfurth (1871), by Stanley (1876) and others, scientific skepticism gave way, grudgingly, to conviction of Du Chaillu's good faith. Many different tribes of pygmies are now recognized as existing in the interior of Africa, all possessing these characteristics: stature ranging from 33 inches to 4 feet 4 inches, as reported

of the Wambutti by Stanley; Schlichter makes the average stature 4 feet 6 inches; complexion, from yellowish brown to reddish brown; usually heavy growth of hair on body and face—a curious item of accordance with the report of Ctesias regarding the pygmæi of India, who had "beards and hair so long as to serve for vesture"; retreating forehead, prognathic jaw; fingers long, tapering, and feet strongly arched; in their villages the huts (8 feet long, 5 feet wide, 4 feet high) are clustered round the hut of the chief; their usual food is vegetable, but they eat almost anything: in hunting they show great intelligence; one tribe, the Wambutti, devise exceedingly ingenious nets, nooses and traps for securing game great and small.

Pyrlades, pî'la-dêz, a legendary Greek hero, celebrated for the friendship which existed between him and Orestes. He assisted Orestes in murdering his mother Clytæmnestra, and eventually married Electra, the sister of his friend. See ORESTES.

Pyle, pil, Howard, American artist and author: b. Wilmington, Del., 5 March 1853. He combines literary and artistic talent and in this double capacity began his career in New York city by contributing to various periodicals. Having achieved a position he returned to his native place where he has resided since 1879. He has been instructor at the Drexel Institute, Philadelphia, but his time is largely occupied with original productions for current periodicals. In art he especially affects scenes of colonial life and of mediæval folk-lore and is remarkably successful in conveying their spirit. Some of the finest achievements in color printing in the magazines of recent times have been from his drawings. Works of which he is both author and illustrator are 'The Merry Adventures of Robin Hood' (1883); 'Pepper and Salt, or Seasoning for Young Folks' (1885); 'Within the Capes' (1885); 'The Wonder Clock' (1887); 'The Rose of Paradise' (1887); 'Otto of the Silver Hand' (1888); 'A Modern Aladdin' (1891); 'Jack Ballister's Fortunes' (1894); 'Twilight Land' (1895); 'Semper Idem' (1903). He also wrote 'Rejected of Men' (1903), the story of the Christ in modern setting.

Pylos, pî'lôs, or **Pylus**, three ancient Greek cities. (1) Pylos in Elis, on the Peneus and Ladon, was an outpost of the Eleans. (2) Pylos in Triphylia, modern Biskini, east of Mount Minthus, was reckoned Nestor's city by Strabo; but this honor is now generally bestowed on (3) Pylos, a city on the western coast of Messenia, on the present gulf of Navarino. If this identification be accepted, Pylos must have been a flourishing city in Homeric times. It resisted Sparta after the second Messenian war, and upon the fall of Ira the inhabitants deserted the city and settled mostly in Sicily. The Athenian general Demosthenes seized the ruined city early in the Peloponnesian war, 424, intending to make it the rallying point for the Messenian disaffection against Sparta. He got a strong position on the eminence called Coryphasium, but was hemmed in on land and sea by the Spartans, who made Sphacteria their base. Demosthenes beat them back by land, the Athenians defeated the Spartan fleet and the Athenians perfected the blockade of the island of Sphacteria. Demosthenes, reinforced by Cleon, who took all the

glory, burned the woods on the island and forced the Spartans to surrender. (See PELOPONNESIAN WAR.) The city was rebuilt by Epaminondas, who attempted to raise up a new Messenian nation. The present name is Navarino, either because of an Avar colony (so originally Avarino) or because of a Navarrese settlement in 1381. See NAVARINO.

Pym, pīm, John, English statesman: b. Brymor, Somersetshire, 1584; d. London 8 Dec. 1643. He was educated at Oxford, and in 1602 entered the Middle Temple, but was never called to the bar. He became member of Parliament for Calne in 1621, but from 1625 sat for Tavistock. He was prominent in the impeachment of the Duke of Buckingham in 1616, and in 1639, with several others, held close correspondence with the commissioners sent to London by the Scottish Covenanters. When Parliament met again in 1640, Pym was one of its most active and leading members, and in the Long Parliament, which met later that same year, he came most prominently to the front. Possessed of great eloquence, he made a vigorous and effective speech as soon as Parliament had opened, dwelling at length upon the grievances of the nation with respect to parliamentary privileges and civil and religious liberty. A few days after he followed up his speech by bringing a charge of high treason against the Earl of Strafford, prime minister of Charles I.; and in the impeachment which followed, resulting in the death of Strafford, he took the leading part. In 1641 a motion was carried by the opposition party to submit a remonstrance to the king exposing the defects of his administration since ascending the throne, and the zeal of Pym in this matter led Charles into the imprudent measure of going to the Parliament in person to seize him and four other members. Clarendon relates that Charles I., feeling the necessity of gaining at any cost an enemy at once so implacable and so skilful, offered to Pym the post of chancellor of the exchequer. In November 1643, he was appointed lieutenant of the ordnance, but died the following December. He was buried with great pomp in Westminster Abbey. Consult: Forster, 'Statesmen of the Commonwealth' (1841-4); 'The Arrest of the Five Members' (1860); and 'The Debates on the Grand Remonstrance' (1860); Goldwin Smith, 'Three English Statesmen' (1867); S. R. Gardiner, 'The Great Civil War' (1893).

Pynchon, Thomas Ruggles, American Protestant Episcopal clergyman and physicist: b. New Haven, Conn., 14 Jan. 1823. He was graduated from Trinity College in 1841, was lecturer on chemistry there 1843-7, studied for the ministry, and was ordained priest in 1849. In 1849-55 he was in charge of parishes in Stockbridge and Lenox, Mass., and in 1854 accepted the chair of chemistry and natural science at Trinity College which he held until 1877 when he exchanged for the chair of moral philosophy. He was president of the college 1874-83. In 1874-8 he superintended the erection of the college buildings on the west side of the quadrangle and the transfer of the college to the new site. While in Europe 1855-6 he made a tour through southern France, Italy, and Sicily, engaged in geological investigations, made a study of volcanic action, and ascended Mount Ætna at

night. In 1902 he became professor emeritus at Trinity. He is a member of the American Academy of Arts and Sciences, was one of the founders of the Meteorological Society, of which he is vice-president, and is connected with various other scientific societies both American and foreign. He has published: 'Treatise on Chemical Physics' (1869); 'An Examination of Bishop Butler's Analogy' (1890).

Pynchon, William, American colonist and religious writer: b. Springfield, Essex, England, 1590; d. Wraybury, England, 29 Oct. 1662. He was a man of education, one of the grantees of the Massachusetts charter and came to America with Governor John Winthrop in 1630. He held various offices in the colony, from 1632 to 1634 acting as treasurer. He first settled at Roxbury as one of the founders of the village and organizers of the church, but withdrew in 1736 with the company led by Rev. Thomas Hooker and Rev. Samuel Stone southward into Connecticut. Pynchon with his family and a small party settled at the junction of the Agawam and Connecticut rivers and founded the present town of Springfield. For several years this place was included in the Connecticut colony and Pynchon sat in its legislature, but in 1641, under Pynchon's influence, the Massachusetts court assumed jurisdiction. In 1650, during a visit to England, Pynchon published a book entitled 'The Meritorious Price of our Redemption.' In this the author took an anti-Calvinistic view of the atonement and so stirred up the colonists that the book was ordered to be burnt and the author cited to appear before the general court. His letter of explanation was deemed unsatisfactory and after being summoned a second time he left the colony in September 1652 and returned to England. He passed the remainder of his life at Wraybury, near Windsor. His earlier book was republished with a rejoinder to the Rev. J. Norton, as 'The Meritorious Price of Man's Redemption' (1655). He also wrote 'Jews Synagogue' (1652); 'How the first Sabbath was ordained' (1654); 'Covenant of Nature made with Adam' (1662). Consult: Green, 'Springfield, 1636-1886: History of Town and City' (1888).

Pypin, Alexander Nicolaevitch, Russian scholar, historian and author: b. at Saratoy in 1833; d. Saint Petersburg 9 Dec. 1904. Received his academic education at the University of Saint Petersburg, where he was appointed to a professorship in 1860, resigning two years later to enter the literary field. He contributed largely to the *Sovremennik* ("Contemporary"), 1865-7, and from then until his death to the *Vestrik Evropy* ("European Messenger"). His first work, a comparative study of Russian, Byzantine and Roman folk-lore, was published in 1859, followed by a 'History of Slavonic Literatures' (1865), 'The Intellectual Movements in the First Half of the 19th Century,' and a masterly biography in two volumes of Byelinski, the critic, in 1876. A four-volume work, 'The History of Russian Ethnography,' was published in 1892-4, and the 'History of Russian Literature' in 1898-9. In 1897 he was appointed a member of The Academy of Sciences of Saint Petersburg, publishing for them the works of Catharine II.

Pyral'idæ, a family of moths (q.v.).

PYRAMID

Pyramid, in architecture, a structure of masonry generally having a rectangular base and four triangular sides terminating in a point. According to Herodotus the Egyptians considered the pyramidal form as an emblem of human life; the broad base was significant of the beginning, and its termination in a point of the end of our existence in the present state; for which reason they made use of this figure in their sepulchres. The most remarkable pyramids are those of Egypt and Nubia and those of Mexico. The Egyptian pyramids have for ages been a source of interest and curiosity, and in ancient times were regarded as forming one of the seven wonders of the world. They are built mainly of a hard limestone, but large blocks of granite are also used, especially on the outside. The four sides are so placed as to face the four cardinal points. Being intended both as monuments and as tombs, they contain one or more sepulchral chambers, quite small compared with the total mass. They appear to date from the period of the 3d dynasty to the 12th (say 2500-2000 B.C.), after which none were built. Each pyramid was commenced over a sepulchral chamber excavated in the rock, and the work went on during the lifetime of the king for whom it was intended. A low narrow passage was kept open as the tiers of stone were added, in order that access might be obtained to the central chamber from without; and when the monarch died the work ceased, and the last layers were then finished off and the passage closed up. The angles formed by the recession of each superior layer were filled up with small stones and beveled off, so as to give a smooth sloping surface to the sides. The stones used varied in thickness from 2 feet to 4 feet, and the mechanical skill requisite to quarry these and to raise them to such great heights and adjust them in their proper places continues a matter of universal astonishment. No indication of the mechanical contrivances used for this purpose has been left, though that they possessed such can hardly be doubted. The fact that an almost fabulous number of laborers were engaged in erecting these pyramids did not lessen the necessity for the employment of certain machines. The pyramids now standing, all in Middle Egypt, are divided into five groups, containing in all about 40 pyramids. The district in which the pyramids stand begins above Dashur, and extends by Sakkara and Memphis along the western margin of the valley of the Nile for about 60 or 70 miles, the last or Gizeh group being but a few miles above Cairo. The group of Gizeh, in the neighborhood of the ancient Memphis, is the most remarkable. It consists of nine pyramids, and comprises the three most celebrated monuments of the kind in existence, namely, the pyramid of Cheops, called the Great Pyramid; that of Cephren, and that of Mycerinus—the last much smaller than either of the others. According to Herodotus the Great Pyramid was built by Cheops. It took 100,000 men working for 10 years to make a causeway 3,000 feet long, to facilitate the transportation of the stone from the Turah quarries; and the same number of men for 20 years more to complete the pyramid itself. Herodotus further describes the method of building by steps, and raising the stones from layer to layer by machines, and finally of facing the external portion from the

top down. Diodorus calls the builder of this pyramid Chemthes or Chabryes, and by Manetho and Eratosthenes he is called Suphis. The latter name corresponds to Shufu, deciphered from the hieroglyphics upon some stones discovered by Colonel Vyse in his important investigations of this pyramid in 1835. The pyramid at present covers an area of more than 12 acres. The base is about 750 feet square, but was formerly about 768 feet. The perpendicular height, which before the disappearance of the apex was about 482 feet, is now 451 feet. The area at the top is about 12 yards square. The outer casing of small stones has been removed, and the appearance the sides now present is that of a series of ascending steps. By these steps, which number 203, the ascent is made comparatively easy, though the lower ones are 4 feet 10 inches high. The content of solid masonry has been estimated at 82,111,000 cubic feet. The only entrance is on the north face, 49 feet above the base, though the masonry about it has been so much broken away that the débris reaches nearly up to it. A passage 3 feet 11 inches high and 3 feet 5½ inches wide conducts from the entrance down a slope at an angle of 26° 41', a distance of 320 feet 10 inches, to the original sepulchral chamber, commonly known as the subterranean apartment; it is carried, reduced in dimensions, beyond this a distance of 52 feet 9 inches into the rock, though for what purpose remains a matter of conjecture. The sepulchral chamber is 46 feet long by 27 feet wide, and 11½ feet high. From the entrance passage another branches off and leads to several other passages and chambers. One of the latter, known as the queen's chamber, is situated about the centre of the pyramid, 67 feet above the base; it has a groined roof, and measures 17 feet broad by 18 feet 9 inches long, and 20 feet 3 inches high. The other, called the king's chamber, is reached by an offshoot from the queen's passage, 150 feet long. Its dimensions are 34 feet 3 inches long by 17 feet 1 inch wide, and 19 feet 1 inch high. The chamber is lined with red granite highly polished, single stones reaching from the floor to the ceiling, and the ceiling itself is formed of nine large slabs of polished granite extending from wall to wall. The only contents of the apartment is a sarcophagus of red granite, which, judging by its dimensions, must have been introduced when the building was proceeding. It is supposed to have contained a wooden coffin with the mummy of the king, and that these long since disappeared when the pyramids were first opened and plundered. The second pyramid, built by Suphis II. or Cephren, stands on a higher elevation than the Great Pyramid. Its original dimensions were 707 feet 9 inches square, and 454 feet 3 inches high; but these now stand 600 feet 9 inches and 447 feet 6 inches respectively, with an angle for its slope of 52° 20'. Part of the outer casing of the pyramid is still preserved. This pyramid has two entrances, and the passages to which they respectively give access lead to the same sepulchral chamber, in which is deposited a granite sarcophagus. It was reached with great difficulty by Belzoni in 1818. Belzoni found in it a Cufic inscription recording the visit of the Caliph Alaziz Othman Ben-Yusuf, and the opening by him of the pyramid in 1196 A.D. The only remains met with were those of a bull. The third pyra-

PYRAMID — PYRENEES

mid, built by Menkaré or Mycerinus, is only 354 feet 6 inches square and 203 feet high. It also was explored by Colonel Vyse in 1837. He discovered several chambers, one of which contained a sarcophagus and a mummy case bearing the name of King Menkaré, and also a body, supposed to be that of an Arab. The two latter are now in the British Museum, but unfortunately the sarcophagus was lost by the sinking of the vessel in which it was being transported to this country. This pyramid is the best constructed of the three; it was originally cased half-way up with black granite. The six smaller pyramids which complete the Gizeh group are supposed to form the tombs of some of the relatives of the kings who constructed the larger ones, and are of much inferior interest to the three above mentioned. Of the other groups of pyramids that at Abusir contains five; another at Sakkara contains eleven, one with a doorway inlaid with porcelain tiles and having a royal name; and a third group at Dashur contains five. Other pyramids are at Meydun and Illahun, and there are two at Bialmu. The pyramids of Nubia are very numerous; a single group north of Gebel Barkal comprises no fewer than 120. In Babylonia the Birs Nimrud or Tower of Belus was a kind of step-shaped pyramid, built of bricks of different colors. It was erected by Nebuchadnezzar, and dedicated to the planets. Its height was 235 feet and its circumference 2,286 feet. The Mujellibe in Babylon, of which the ruins are still to be seen, was another pyramidal structure of the same monarch. Ruins of pyramids are to be found at Benares in India and in other parts of the East. Certain monuments of the ancient inhabitants, found in Mexico, are also called pyramids. (See MEXICAN ARCHAEOLOGY.) Consult: Lepsius, 'Ueber den Bau der Pyramiden'; Vyse, 'Operations carried on at Gizeh in 1837'; Petrie, 'The Pyramids and Temples of Gizeh' (1884); Maspero, 'L'Archéologie Egyptienne' (1887).

Pyramid, in geometry, a polyhedron with a polygon as base, and triangular sides meeting in a common point called the vertex. The regular pyramid is bounded by four equilateral triangles with the vertex perpendicular to the centre of the polygonal base, and is thus a tetrahedron. The perpendicular distance between the base and the vertex is the altitude. The *slant* altitude is the height of any of the triangular sides. Pyramids are named according to the natures of their bases; they may be triangular, quadrangular, etc., according as their bases are triangles, quadrilaterals, pentagons, etc. The base and lateral triangles are called faces; the lines in which the faces meet are called edges; the points in which the edges terminate are called the vertices of the pyramid.

Pyramus (pī'r'a-mus) and **Thisbe**, thīz'bē, a pair of unfortunate lovers whom classical legend represents as living in Babylon. Their parents were enemies and would not sanction the marriage of the lovers, but the two contrived to converse with each other in secret through an opening in the walls of their adjoining houses. They finally determined upon a meeting at the tomb of Ninus. Thisbe was first to arrive and meeting a lioness who had just killed an ox she ran away, dropping her mantle in her flight. This the lioness soiled with blood and

Pyramus arriving shortly after and finding the blood-stained garment of his betrothed imagined her to have been killed and ended his life beneath a mulberry tree, the fruit of which has since been of a blood-red hue. Thisbe returning finds the body of her lover, whereupon she then kills herself in despair. The legend is embodied in Ovid's 'Metamorphoses' and is caricatured in the farcical interlude in Shakespeare's 'Midsummer Night's Dream.'

Pyrargyrite, pī-rār'jī-rīt ("dark ruby silver"), a rhombohedral mineral, usually of high metallic-adamantine luster, color black by reflected light, rich ruby-red by transmitted light, hardness 2.5, specific gravity 5.85. It is a silver sulph-antimonite, containing 60 per cent of silver. It occurs in magnificent specimens in Germany, Mexico, Chile and Bolivia, and is an important silver ore in these countries and in the mining regions of the Western United States.

Pyrenees, pīr'e-nēz, a lofty mountain chain forming the boundary between France and Spain. Its length, from Cape Creux, north of the Gulf of Rosas, to the Point of Figuiér, near Fuenterrabia, is nearly 270 miles; and its breadth near the centre, where it is greatest, scarcely exceeds a third of the length. Though the chain thus defined terminates at two opposite seas, it cannot be said to be isolated, since to the west it is obviously continued across the north of Spain by the Cantabrian Mountains. The direction of the chain is east-southeast, to west-northwest. It does not, however, lie in the same straight line, but rather consists of two lines, which form parallel ridges about 20 miles distant from each other, except near the centre, where they become united by means of a remarkable rectangular elbow, in which some of the loftiest summits are found. Both on the north and south sides numerous branches are thrown off, generally at right angles to the principal axis, and subside rapidly as they recede from it, forming various transverse, but very few longitudinal, valleys. The chain rises both from the east and west toward the centre; and, in accordance with a general rule which holds in regard to the European chains, which lie in the direction of the equator, the descent on the south side is much more abrupt than on the north. Owing to this the south has much fewer lakes than the north slope, but far surpasses it in the boldness and grandeur of its scenery. As already observed, the loftiest summits of the chain are near its centre. Its culminating point, Maladetta, situated there, has the height of 11,168 feet, and a great number of peaks in the same locality exceed 8,500 feet. To the east of the centre the chain lowers so rapidly that its average height soon becomes little more than 2,000 feet. To the west the height diminishes much more gradually, and many peaks have heights varying from 5,000 to 7,000 feet, and even 8,000 feet. The principal passes in the Pyrenees formed by the meeting of valleys from opposite sides of the axis, take in the east part of the chain the name of Cols, and toward the centre that of Ports. No fewer than 75 are counted, of which 28 may be crossed on horseback, and 7 in wheeled carriages. The most frequented are those of Pertus and La Perche in the east, and St. Jean Pied de Port in the west. The nucleus of the chain is evidently granite, which.

THE GREAT PYRAMIDS, NEAR CAIRO.

with the primitive schists which overlie it, constitutes the loftiest summits, with the exception of Mont Perdu (10,994 feet), Marbore (10,673 feet), and some huge adjacent masses which are formed of mountain limestone. The granite, however, seldom forms continuous ridges along the principal axis, but rather appears in a number of remarkable protuberances situated to the north of it. Above the micaceous schist and primitive limestone, which occur in connection with it, lie largely-developed strata of argillaceous schist and transition limestone, forming two great belts parallel to the primitive chain, one on the north and the other on the south side. Above these secondary rocks appear, of which by far the most common is the mountain limestone, which occupies the greater part of the south slope, but on the north side attains little elevation, being there almost entirely confined to the lower heights at the bottom of the principal chain. Above the mountain limestone the principal rocks are Jura limestone and trap. The number of thermal springs existing in the Pyrenees seems to indicate the presence of volcanic agents, but basalt and other rocks of igneous origin are very rare. The minerals of the chain include iron, copper, lead, zinc, manganese, antimony, and cobalt. There is no mine either of silver or gold, but particles of the latter are found in department Ariège, and in the streams of several other districts. The only mineral which has hitherto been worked to much advantage is iron. Mineral springs, both cold and thermal, are numerous, and much frequented by visitors. The limit of vegetation on the Pyrenees is about 600 feet higher than on the Alps. The rhododendrons, which in the latter are not found higher than 5,000 feet, are here found at 5,500 feet, and alpine plants are found on the loftiest summits bordering on the region of perpetual snow. In the Pyrenees this is found only on the north slope, where it does not, as in the Alps, form a snowy zone, the lower limit of which looks as if traced out by an almost horizontal straight line; but, on the contrary, forms large isolated masses, the base of which is often concealed by the mountains in front of them. This makes it difficult to fix the snow-line with precision, but according to the most accurate estimate it is 9,190 feet, or nearly that of Mount Canigou. Glaciers are not numerous in the Pyrenees, and hence the torrents and rivers which rise in the chain are fed chiefly by springs. Those on the south side flow toward the Ebro, and are carried by it to the Mediterranean; those on the north side flow partly to the Mediterranean and partly to the Atlantic, the water-shed between the two seas being carried northward by a branch which ultimately links with the Cevennes. The largest river of the chain, and the only one of importance which preserves its name throughout its whole course, is the Garonne. In respect of average height and mass the Pyrenees are unquestionably the second mountain chain of Europe, but its culminating point, Maladetta, has only the third place, being indeed lower than Mulhacen in the Sierra Nevada. Contrary to the general rule, that the loftiest summits of mountain chains are found in the line of the principal axis, Maladetta, Posets (11,047 feet), and Mont Perdu, the three culminating points of the Pyrenees, are situated on the south slope.

Consult: Taine, 'Voyage aux Pyrénées,' especially the 4th ed. (1873) with illustrations by Doré; Schrader, 'Les Pyrénées,' in the 'Annuaire du Club Alpin français' (1885); De Margerie and Schrader, 'Aperçu de la Structure géologique des Pyrénées' (1891), and 'Aperçu de la Forme et Relief des Pyrénées' (1892); Camena d'Almeida, 'Les Pyrénées: Développement de la Connaissance géographique de la Chaîne' (1893); Trutat, 'Les Pyrénées' (1894); Bubanus, 'Flora Pyrenæa' (1897-1902); Spender, 'Through the High Pyrenees' (1898).

Pyrenees, Peace of the, in European history, the name given a treaty concluded between France and Spain by Cardinal Mazarin and De Haro, on the Ile des Faisans, in the river Bidassoa, 7 Nov. 1659, terminating a war which had lasted for 24 years. By this treaty Spain ceded to France Roussillon, with the fortress of Perpignan, etc., so that the Pyrenees have since formed the boundary of the two kingdoms; and in the Netherlands, Artois, and part of Flanders, Hainault, and Luxemburg, with a number of fortified towns.

Pyræthrum, a group of composite plants formerly considered a genus but now ranking as a section of the genus *Chrysanthemum*. In garden literature the name is generally restricted to *Pyrethrum roseum*, several hundred varieties of which are widely popular in European gardens. Under the name *Chrysanthemum coccineum* it is extensively cultivated in southern France, California and western Asia for its flowers, which are dried and ground as the material of insect powder. Another species (*C. cinerariifolium*) is also cultivated for this purpose. The well-known bedding-plant "golden feather" is a variety *C. prælum*, but is widely known as *Pyrethrum aurcum* among horticulturists. The plants are easy to grow in any good garden soil, if deeply dug and highly enriched. Since the seed is often disappointing in its results, the plants are best propagated from choice varieties by division in the spring. The golden-feather pyrethrum is often propagated by cuttings made during the winter from stock plants.

Pyrgos, pir'gōs, Greece, capital city of the nomos of Elis, 13 miles west of Olympia, on the west coast of the Morea, near the mouth of the Ruphia (Alpheus), on the railroad from Piræus to Olympus, and with branch connections with its harbor, Katakolon. The surrounding country is a fertile plain, growing currants, oranges, and grapes. The commune in 1896 had a population 26,771; the town, 12,708.

Pyrheliometer, an instrument for measuring the intensity of the heat of the sun. It is a shallow, circular vessel of silver, having one side coated with lampblack, containing mercury or water, and having a thermometer let into it.

Pyr'idine (C₅H₅N), a mobile liquid, boiling at 117°, obtained by the distillation of various organic substances, such as peat, bone, coal naphtha, etc. It has an alkaline reaction, and forms salts with acids.

Pyrite, or **Iron Pyrites**, the commonest metallic mineral, like copper pyrites, is often called "fool's gold," owing to its resemblance to gold. It may readily be distinguished by its much greater hardness, 6 to 6.5, brittleness, pale brass-yellow color, greenish-black streak, and

specific gravity, 4.95 to 5.10. It crystallizes in isometric crystals often of great beauty, but is usually found massive as a vein material or in beds of great extent. It is an iron disulphide, FeS_2 . Its high sulphur percentage, 53.4, and the ease with which it may be burned, leads to its enormous consumption in the manufacture of sulphuric acid. Owing to its ready oxidation, it is an active agent in the disintegration of those rocks through which it is disseminated. It frequently contains gold and to some extent other valuable metals. Its most importance commercial occurrence is at Rio Tinto, Spain. It is also extensively mined near Rowe, Mass., in Virginia, the Carolinas, Georgia, Colorado and in many other regions. The finest crystals come from Elba, Cornwall in England, Peru, Chester County, Pa., and Central City, Colo.

Pyrites, either of the various metallic sulphides, of which the most important is iron pyrites (see **PYRITE**). Copper pyrites (see **CHALCOPYRITE**) is an important ore of copper. Arsenical pyrites (see **ARSENOPYRITE**) furnishes much of the arsenic of commerce; magnetic pyrites (see **PYRRHOTITE**) is often an important nickel ore.

Pyrmont, pēr'mönt, Germany, a celebrated watering-place of Prussia, in the principality of Waldeck and Pyrmont, capital of the district; in a beautiful valley at the foot of a range of finely wooded hills, on the left bank of the Emmer, 34 miles south-southwest of Hanover. It contains a palace, in which the Prince of Waldeck and Pyrmont resides during the watering season; and it is much frequented, particularly by the aristocracy of Germany; from 10,000 to 20,000 visitors are here annually. One of the curiosities of the place is the Dunsthöhle or gas grotto, which emits vapors similar in nature and effect to those of the Grotto del Cane in Italy. Pop. (permanent) 1,500.

Pyrochlore, a dark brown, resinous mineral of complex composition, essentially a cerium and calcium niobate, but of interest because containing also thorium and uranium. It occurs in octahedrons in Norway and Russia.

Pyrogall'ic Acid, **Pyrogallol**, **Tri-oxy-benzene**, $\text{C}_6\text{H}_3(\text{OH})_3$, is produced by action of heat on gallic acid, carbon dioxide being eliminated in the process. Fine colorless needles or plates, readily soluble in water, less so in alcohol or ether, melting point 132°C . Valuable because of its great affinity for oxygen, its alkaline solution is used to absorb oxygen in gas analysis. It is used extensively as a photographic developer, but has the disagreeable power of darkening the skin. It forms a number of derivatives, some being valuable dyestuffs.

Pyrography, from $\pi\upsilon\rho$, fire, and $\gamma\rho\alpha\phi\epsilon\upsilon$, to write, literally to write by fire. A method of making impressions on wood, leather, etc., by means of heated metallic instruments. The art was early practised by the Egyptians who used crude iron bars that had been previously heated in fire. The modern form of this kind of apparatus consists of a tube about six inches in length and about half an inch in diameter provided at its lower extremity with a screw-cap and a small support. At the other end there is a rod to which the drawing point is affixed. For the formation of the combustible gas

and heating of the rod sulphuric ether is usually employed. The gas when generated is forced to the metallic point by means of air pressure and after the flame has been regulated a person may work for two consecutive hours at an expense of about one half cent per hour. The vapors disengage themselves constantly and feed the small flame which is barely perceptible. The heat is always uniform, and even on leather a sure and sharp execution of the design is possible. The effects produced by the pyrograph are equal in many respects to the fine crayon drawings, and when colored and varnished present a very pleasing effect. The finest and most delicate lines can be drawn and there is no danger of burning holes in the material. The right hand being engaged in the execution of the piece to be ornamented leaves the left free to turn the object in any desired position while the work is in progress.

From a commercial standpoint, work in pyrography offers very good returns. It is taught in most of the trade schools, and by many private masters, and those who apply themselves systematically may use their accomplishment with profit. Apart from the artistic and financial interest the work has a substance and lastingness about it that makes it seem worth while to master.

Pyrolig'neous Acid, impure acetic acid produced as one of the volatile products of the destructive distillation of wood. The wood is slowly heated in large iron retorts or ovens so arranged that the volatile products may be condensed and gathered. The watery portion contains wood alcohol and acetic acid mixed with small amounts of such impurities as carbolic acid, creosote, and the like. On redistillation the wood alcohol passes over first, leaving the impure acetic acid or pyroligneous acid in the retort. This may be purified (see **ACETIC ACID**) or used as such for various purposes such as the impregnation of wood to prevent decay, etc.

Pyrolu'site, the most important ore of manganese. It is a black or gray mineral of brilliant metallic lustre. It is distinguished from manganite and polianite, which it much resembles, by being so soft (hardness 2 to 2.5) as readily to soil the fingers. Its black streak further separates it from manganite. While its crystallization is orthorhombic, it is usually massive or radiating-columnar. Chemically it is manganese dioxide, MnO_2 . It has long been used in the manufacture of chlorine and oxygen, and in decolorizing glass; its present most important use is in the preparation of manganese-steel. It occurs abundantly in Thuringia and elsewhere in central Europe, also in Nova Scotia and Brazil. In the United States it is mined in Virginia, Georgia and Arkansas.

Pyroma'nia, incendiary monomania, a form of insanity characterized by an irresistible desire to destroy by fire. In most forms of mental disease self-control is lost, but in pyromania the loss of the power of inhibition is the chief symptom; hence the affection is sometimes spoken of as a form of inhibitory insanity.

Pyrom'eter, an instrument for measuring temperatures higher than the boiling-point of mercury (350°C). Regnault and other careful experimenters employed the expansion of air and vapors in measuring high temperatures. These

pyrometers can only be used in a laboratory; for use in a manufactory less accurate methods of measurement have to be employed. In Wedgwood's pyrometer (1782) it was assumed that dry clay, when exposed to heat, contracted regularly, and the instrument was constructed on this principle; but it is now known to be untrustworthy. An instrument in which the expansion of a metal bar (generally of platinum) was magnified by means of levers has often been employed to measure the temperature of a furnace. Morveau, Brongniart, and Daniell invented instruments on this principle. The thermo-electric law of Tait may be used to calculate the temperature to which a junction of copper and iron has been subjected, the electric current produced being measured by a galvanometer. In this way high temperatures have been measured with considerable accuracy. By Siemens' method temperatures are measured by observing the increased electric resistance of a platinum wire when heated, two coils of the same kind of wire being prepared so as to have equal resistances at the same temperature, their ends connected by rather long thick copper wires, and the current from a constant battery passing through them measured by means of a galvanometer. One of the coils is kept at a known temperature, the other has the temperature which it is desired to measure. The law discovered by Siemens —

$$R = \alpha \sqrt{T} + \beta T + \gamma$$

where R is the resistance at the absolute temperature T , and where α , β and γ are certain numbers, enables the temperature to be calculated. Pouillet determined the following temperatures by means of an air-thermometer. They correspond to the stages of incandescence of a metal bar.

| | |
|--------------------------|---------|
| Incipient red-heat | 525° C. |
| Dull red | 700° |
| Cherry red | 900° |
| Dark orange | 1100° |
| White | 1300° |
| Dazzling white | 1500° |

Pyromor'phite, a mineral occurring in hexagonal crystals, often cavernous and barrel-shaped, or in curious nearly parallel groups tapering to a point. It is a lead phosphate and chloride and occasionally occurs in sufficient quantities to be an important lead ore. Its hardness is 3.5 to 4, specific gravity, 6.5 to 7.1, color commonly green, yellow or brown, lustre resinous. Its most notable occurrences are Ems, Germany; Cumberland, England; Broken Hill, New South Wales, and in the United States formerly at Phoenixville, Pa.

Pyrope, or **Bohemian Garnet**, a fine dark-red variety of garnet, often called "precious garnet" because of its extensive use as a gem. Peridotite, or serpentine derived from it, is the usual matrix of pyrope in Bohemia and in Kimberley, South Africa, but more commonly it occurs as rounded pebbles loose in the sands, as in the ant-hills of the Navajo Reservation in Arizona. It is often incorrectly called "ruby." See CARBUNCLE.

Py'rophone, a musical instrument, in which the various notes are produced by the burning of hydrogen gas within glass tubes of various sizes and lengths. It is also called a flame-organ, and was invented about 1875 by a Frenchman called Kastner.

Pyrophyllite, or **Pencil Stone**, a mineral of soapy feel, the compact form of which is extensively mined in North Carolina as soapstone. Its uses are the same as those of the related mineral talc (q.v.). Some of the almagatolite used by the Chinese for carving into pagodas and images is pyrophyllite. The mineral is usually found in coarse lamellar radiations, occurring thus in fine specimens in Switzerland, Georgia, North Carolina and California. Chemically, it is a hydrous aluminium silicate.

Py'roscope, an instrument for measuring the intensity of heat radiating from a hot body, or the frigorific influence of a cold body. It is constructed on the same plan as a differential thermometer.

Pyro'sis, or **Waterbrash**, a disorder of the stomach attended with a sensation of burning in the epigastrium, commonly called heartburn, accompanied with an eructation of watery fluid, usually insipid, but sometimes acrid. See DYSPEPSIA.

Pyrotech'nics, a term applied to the composition, structure, and use of fire-works. The ingredients are nitre, sulphur, and charcoal, together with filings of iron, steel, copper, zinc, and resin, camphor, lycopodium, etc. Gunpowder is used either in grain, half crushed, or finely ground, according to the desired effect. The proportions of the materials differ very much in different fire-works, and the utmost care and precaution are necessary in the manufacture. Lampblack produces a very red color with gunpowder, and a pink with nitre in excess. It serves for making golden showers; yellow mica-ceous sand serves for the same purpose. Verdigris imparts a pale green, sulphate of copper and sal-ammoniac a palm-tree green. Camphor produces a very white flame, with aromatic perfumes, which mask the bad smell of the other ingredients; benzoin and storax are also used on account of their agreeable odor. Lycopodium, which is often used in the manufacture of stage-lightning, burns with a rose color and a magnificent flame. Sky-rockets, an important feature of pyrotechnics, will be found fully described in the article PROJECTILES.

Py'roxene, a mineral formed commonly in crystalline limestone or dolomite, in serpentine and in rocks of volcanic origin. Less abundant in granitic rocks and metamorphic schists. Crystalline form, monoclinic. Brittle. Hardness, 5 to 6. Specific gravity, 3.2 to 3.6. Of a vitreous or resinous lustre. Color is usually some dull shade of green, but may vary to nearly colorless or to brownish black. Composition, a metasilicate, $RLiO_3$, where R is Ca, Mg, Fe, sometimes Mu or Zn, rarely the alkali metals. Important varieties of pyroxene are diopside, hedenbergite, schefferite, augite. Pyroxene is one of the most important of the rock-forming minerals, being an essential constituent of basalt, diabase, trachyte, syenite, gabbro, pyroxenite and many other rocks. It is thus widely distributed in all parts of the world. Especially fine crystals occur in the Piedmont, in Sweden, northern New York and southern Canada, and in New Jersey.

Pyroxene Group, a name given to a group of minerals of which the mineral pyroxene is an important member. Composition, simple silicates of the type $RSiO_3$ where R is Ca, Mg, Fe, sometimes Mu, or Zn, or compound silicates of

the types $R''(\text{FeAl})_2\text{SiO}_3$ or $R'\text{Al}(\text{SiO}_3)_2$. While the species included in the pyroxene group belong to three distinct crystal systems—orthorhombic, monoclinic, and triclinic—they all have a prismatic angle of 87° , parallel to which cleavage is usually eminent. They are distinguished further by their optical properties. The most important species in the pyroxene group are enstatite, hypersthene, pyroxene, acmite, spodumene, wollastonite, pectolite, and rhodonite.

Pyrox'ylin. See GUN-COTTON.

Pyrrhic (pĭr'ĭk) **Dance**, a famous war-dance of antiquity. It was danced to the sound of the flute, and its time was very quick and light. It was introduced into the Roman public games by Julius Cæsar, and was danced by male and female dancers, having much of a dramatic character. In the mountainous districts of Thessaly and Macedonia a dance called the Romaika, which is supposed to be a modern relic of the Pyrrhic dance, is performed by men armed with muskets and swords.

Pyrrhic Victory, so called from the defeat of the Romans at Asculum 279 B.C. by Pyrrhus, whose losses however were so heavy that the term has become proverbial for a fruitless victory.

Pyrrho, pĭr'ō, Greek philosopher: b. Elis about 376 B.C.; d. about 270 B.C. He was a pupil of the Democritean philosopher Anaxarchus of Abdera, whom he accompanied to India in the train of Alexander the Great. During this journey he became acquainted with the doctrines of the Brahmans, Magi, and other eastern philosophers. His doubts concerning positive knowledge were strengthened as he proceeded in his studies, until at length he came to hold all knowledge uncertain, and considered virtue alone as valuable. In all disputes his answer to his opponents was, "What you say may, or may not, be true; I cannot decide," and he taught in his school that truth could not be attained, and that we must be content to suspend our judgment on all subjects. He spent much of his life in solitude, and by abstaining from all decided opinions concerning moral and physical phenomena, endeavored to attain a state of tranquillity unaffected by fear, joy, or sorrow. His countrymen, the Abderites, made him high-priest, and exempted all philosophers from the payment of taxes. The Athenians erected a statue in honor of him, and his countrymen raised a monument to his memory. His skepticism is easily accounted for. His master, Democritus, held that except the immediate elements of bodies (atoms) nothing was real, and that all perception was subjective. He was confirmed in these views by the doctrines of Socrates, to whom, in his character, he bore great resemblance, and his skepticism is allied to the irony of that philosopher. Led by his temperament and manner of life to esteem uninterrupted tranquillity the great object of all philosophy, believing that nothing tended so much to destroy this quiet as the interminable disputes of the schools of the dogmatists, and that uncertainty was increased by their contentions, he determined to seek in some other way the peace which he despaired of finding in dogmatical philosophy. A disposition to doubt is often called, from this philosopher, Pyrrhonism.

Pyrrhonists. See RELIGIOUS SECTS.

Pyrrhotite, pĭr'ō-tīt, or **Magnetic Pyrites**, a metallic mineral, in composition an iron sulphide, probably $\text{Fe}_{11}\text{S}_{12}$, differing from common iron pyrites, FeS_2 , in percentage composition, in being attracted by the magnet, in its bronze color, inferior hardness (3.5 to 4.5), and specific gravity (4.6). It rarely crystallizes in hexagonal, tabular crystals; usually it occurs massive. Though pyrrhotite contains over 60 per cent of iron and nearly 40 per cent of sulphur, it is only very recently that it has been regarded as of any value for these ingredients. Its commercial value was due entirely to the occasional presence as an impurity of varying percentages of nickel. Formerly the deposits of nickeliferous pyrrhotite at the Gap Mine, Pennsylvania, were extensively worked, but the far richer and more extensive deposits at Sudbury, Ontario, are now the chief sources of nickel. Enormous beds of copper-bearing pyrrhotite, nearly free from nickel, are successfully worked in Vermont. Choice crystallized specimens are found in Austria, Brazil, and at Tilly Foster, New York.

Pyrrhus, pĭr'ūs, Greek military leader, king of Epirus: b. about 318 B.C.; d. Argos 272 B.C. He was the son of Æacides, who traced his descent from Pyrrhus, son of Achilles. He spent an eventful youth, regained the throne from which his father had been deposed, and was himself expelled several years later. He became the friend of Demetrius Poliorcetes, whom he accompanied on the fatal campaign closed by the battle of Ipsus (301 B.C.), then proceeded to Egypt as hostage for Demetrius, and there married Antigone, daughter of Queen Berenice. With the aid of Ptolemy Soter he recovered his kingdom (296), agreeing to share the sovereignty with Neoptolemus, who had been king since his expulsion, but soon after put his colleague to death, and succeeded by courage, affability, and generosity in gaining the admiration of his soldiers and people. He temporarily conquered Macedonia and in 280 went to southern Italy at the head of a large army to assist the Tarantines against the Romans. Near Heraclea, on the Siris, the consul M. Valerius Lævinus was defeated by Pyrrhus, whose elephants played an important part in the conflict. Another battle was won, but his loss led Pyrrhus to say, "Another such victory and I must return to Epirus alone." He made proposals of peace to the senate, which were rejected. After having approached within 24 miles of Rome he returned to Tarentum. In 279 he again defeated the Romans, but was glad to accept the offered truce, and passed with his army into Sicily, where he assisted the Greeks against the Carthaginians. At first he met with brilliant success; but his attack upon Lilybæum failed. The war ended in the following year with the total defeat of Pyrrhus by the Romans under Curius Dentatus, near Beneventum. On this occasion the famous elephants of Pyrrhus rushed back upon his own army and contributed to his loss. He reached Epirus with a small remnant of his once splendid army. Nothing daunted, he again invaded Macedonia, and became its king a second time. He afterward turned his arms against Sparta, but was driven from before the walls of that city. In a night attack made upon Argos he was stunned by a tile thrown by a woman from a

house-top, and being recognized by the enemy's soldiers was slain.

Py'rus, or Pirus, a genus of fruit-bearing shrubs and trees of the rose family. There are about 40 species, natives of the northern hemisphere and especially of the cool temperate parts. They have usually simple leaves, clusters of showy white, pinkish or bluish flowers after the leaves appear, and fleshy fruits (pomes). Horticulturally this is one of the most important of plant genera, since it includes the apple, pear, quince, and medlar (qq.v.). The last two, however, are often separated into distinct genera. Some of the species, as crab apples, are cultivated for ornament.

Pythagoras, pī-thāg'ō-ras, Greek philosopher: b. Samos about 582 B.C.; d. about 507. His father, Mnesarchos, was a merchant (probably of Tyre or some other Phœnician city) who traded with Samos, where he received the rights of citizenship, and settled with his family. The biography of Pythagoras is mingled with many fables. He received his first instruction from Creophilus in his native city. He then went to the island of Scyros, and was a scholar of Pherecydes till the death of the latter; others make him also a scholar of Thales and Anaximander. Iamblichus says that Pythagoras, during his journey to Egypt, spent some time in Phœnicia in intercourse with the successors of Moschus, and other priests of the country, by whom he was initiated into their mysteries, and that he traveled through various parts of Syria in order to become acquainted with the most important religious usages and doctrines. He is said to have been recommended by Polycrates, king of Samos, to the Egyptian king Amasis. In Egypt he became acquainted with the whole range of Egyptian learning. He remained in Memphis and Thebes 22 years, and was in Egypt when that country was conquered by Cambyses. Like many others of the sages in that kingdom, he was carried captive to Babylon, where he conversed with the Persian and Chaldean Magi; and traveled as far as India, and visited the Gymnosophists. After his return he opened a school at Samos, in which he taught his doctrines in a symbolic form, in imitation of the Egyptians. He also visited Crete, where the priests of Cybele took him to the caverns of Ida, in which Jupiter had been cradled. Here he met Epimenides, whom he initiated into the sacred mysteries of the Greeks. From Crete he went to Sparta and Elis, and from thence to Phlius, where, being asked by King Leon what was his profession, he replied that he was a philosopher (or lover of wisdom), declaring that the name of sage (*sophos*) belonged solely to the Divinity. With augmented knowledge he returned home, where he now founded a philosophical school with great success. He laid claim to supernatural powers, and his extraordinary qualities gained over great numbers of the noble and wealthy classes. Three hundred of these were formed into a select fraternity or order, which has been frequently compared with the still more famous order founded by Loyola in modern times. The members were bound by a vow to Pythagoras and each other, for the purpose of cultivating the religious rites and ascetic observances of their master, and of studying his system of philosophy. They thus formed at once a philosophical school and a re-

ligious order, which in time assumed the character and exercised the influence of a political association also. This influence, which became very considerable, was constantly exerted in the interest of the aristocratic party. The democratic party (perhaps, also, at times, an unfriendly aristocratic faction) reacted against the growing power of the order. At the head of this opposition party in Crotona was Cylon, a rich and respectable citizen, whose enmity Pythagoras had excited by refusing to receive him among his scholars. In revenge Cylon once attacked the house of Milo, where a number of Pythagoreans were assembled, surrounded it with his partisans, and set it on fire. Forty persons perished, and but few escaped. Pythagoras was probably not in the house. Other authorities set down this event long after the death of Pythagoras, who, they say, was simply banished by Cylon to Metapontum. He fled to the Locrians, and when these refused to receive him, to Metapontum, where, according to tradition, he perished from hunger. Consult: Lewes, 'Biographical History of Philosophy'; Grote, 'History of Greece'; Zeller, 'Pre-Socratic Schools.'

Pythagoras of Rhegium, rē'jī-ŭm, Greek sculptor: b. Samos toward the end of the 5th century before Christ. He was noted for his skill in giving the finest and justest proportions to his statues which often represented the human body in attitudes most difficult to represent. Such were his 'Limping Philoctetes' (in bronze); his 'Apollo in Combat with the Dragon'; his 'Duel of Eteocles and Polynices'; 'Europa and the Bull.' His favorite subjects were victors in the public games, and it was his habit as an artist to elaborate the details of his figures; he was learned as an anatomist and in his statues the hair, sinews, and even veins were represented with life-like distinctness and individuality.

Pythagore'an Theorem, the 47th proposition of the first book of Euclid's Elements, which shows that in any right-angled triangle the square on the hypotenuse is equal to the sum of the squares on the other two sides.

Pythagore'anism, the philosophical doctrine of the Pythagoreans, or followers of Pythagoras (q.v.). The system of the Pythagoreans was comprehensive and included a theory of being, that is, a metaphysic; a cosmological theory; and a mathematical theory.

Pythagorean Metaphysics.—The Pythagoreans taught that the essence of all things was number; that everything in its final analysis could be resolved into number. This statement, which is recorded in Aristotle's Metaphysics, where he is enumerating the Greek schools of philosophy, has occasioned much dispute. We may perhaps see in this doctrine the basis of the 10 antitheses of Pythagorean teaching, especially that of the opposites, odd and even, the definite and indefinite, which are placed first in the list. Number was also an idea in which these opposites were each included, and was therefore sometimes spoken of as harmony. But other interpretations of the Pythagorean number make unity and duality as the root notion, and pronounce that these terms may be reduced to the opposition of the spiritual and corporeal, of form and substance, of the Supreme Being and the material world. The Deity is the one,

the Original Unity, the Infinite, out of which all finite things have come. The opposition between the limited or finite, and the unlimited or infinite is by some philosophers regarded as the fundamental idea in the Pythagorean number. It is possible that the doctrine was from the first propounded as a vague generalization which might be and was interpreted in different ways by different members of the school. It is evident that nothing can exist without number, as is stated in the apocryphal Book of Wisdom, in some respects a product of Alexandrian Neo-Pythagoreanism. The numbers themselves are divisible into odd and even, and thus suggesting the contrast between the limited and unlimited, the conditioned and the unconditioned, the relative and the absolute, matter and spirit, man and God. On the other hand, it is possible that the Pythagorean number was not arithmetical but geometrical. The great disciple of Pythagoras in the time of Socrates was Philolaus, but of the writings in which he expounded his views only fragments survive, and these are of doubtful authenticity. Philolaus may have been under the influence of Democritus, and his theory of number have been based on geometrical axioms, and the intervals in the sounds struck from the seven-stringed lyre. Probably he was an atomist. The individual atom would in that case represent to him a material spatial point, two of which made a line, three a surface, four a solid; of these solids, represented always by even numbers, the constituents of earth were cubical; those of fire tetrahedral, those of water icosahedral, etc. From the use of numbers as the ontological basis of things the passage was easy enough to the wild and fanciful application of them as mere symbols. Thus the later Pythagoreans made the soul correspond with the number six, while seven was the counterpart of reason and health. The imagination here stepped in and with curious ingenuity labored to give a rational basis to these axioms. Hence the famous oppositions of this philosophical sect; namely (1) limited and unlimited; (2) even and odd; (3) one and many; (4) right and left; (5) male and female; (6) rest and motion; (7) straight and crooked; (8) light and darkness; (9) good and evil; (10) square and rectangle. It will be perceived that in these oppositions the idea of completeness, as represented by an even number, and incompleteness by an odd number is the ruling element, and in the idea of incompleteness is implied the potentiality of indefinite extension, multiplication, or variation.

Pythagorean Cosmology.—Pythagoras, or at least the Pythagoreans, had some vague idea of a heliocentric solar system. They taught that the universe had as its centre a fire round which the earth and stars revolved. This central fire was not identified with the sun; the stars were luminous from reflecting its light. They taught that this fire was not visible from the earth; that there was a counter earth which made up with the five known planets, the fixed stars, sun, and moon to celestial phenomena. The distance of the spheres from the central fire was determined according to simple numerical relationships. The harmony of the spheres was a melodious sound resulting from the revolution of the heavenly bodies in accordance with the intervals of their distance from the central fire. The Pythagoreans dis-

covered the connection between the length of the string in a lyre and the character of the note which was sounded on percussion. They taught the transmigration of souls.

Pythagorean Geometry.—The Ionic school of Greek philosophy imported geometry from Egypt into the Greek world of intellectual activity. Its early development in Europe was mainly due to the followers of Pythagoras, who himself enunciated the theorem now known as the 47th proposition of the first book of Euclid. The three proportions, arithmetical, geometrical, and harmonical were known to them and the so-called most perfect proportions, such as $6:8=9:12$, were familiar to them, having been introduced into Greece by Pythagoras who learned it from its inventors the Babylonians.

Pytheas, pîth'ē-as, Greek navigator: b. Massilia (Marseilles) in the 4th century B.C. He made two voyages of discovery along the western coast of Europe from Gibraltar to Iceland. The first voyage extended along the western coast of Europe, through the English Channel, and after somewhat extensive explorations in Britain he proceeded northward and reached Thule, which seems identical with Iceland. Here he was deterred from farther advance by dense fogs and considered himself to have reached the point where the earth ended. He described the fog as a molluscous substance, in which earth, air, and sea mingled and in which the universe was suspended. His second voyage seems to have extended along the coast of Denmark and to the Baltic. His accounts of his voyages were received as fables by the ancients, and, though celebrated as a navigator and mathematician, little is known of him excepting through the brief and adverse criticism of later writers, among whom are Strabo and Pliny. His accounts were without doubt in the main correct, but the loss of his works makes it difficult to ascertain his real status. He was said to have been the first to determine the sun's meridian altitude at Marseilles at the summer solstice by means of a gnomon. The scanty fragments remaining of his writings were published by Arvedson (1824).

Pyth'ian Games, in ancient Greece, a name given one of the four seasons of games, instituted in early times in honor of Apollo, the conqueror of the Python. They were celebrated in the neighborhood of Delphi (formerly called Pytho), in the Crissæan fields, which for this purpose contained a hippodrome or race-course; a stadium of 1,000 feet in length; and a theatre, in which the musical contests took place. According to the popular mythological legend the Pythian Games were instituted by Apollo himself. They seem to have been originally only a musical contest, which consisted in singing a hymn to the Pythian god. Until about 586 B.C. they were under the management of the Delphians, and took place at the end of every eighth year; but after that date they were conducted by the Amphictyons, and were celebrated at the end of every fourth year, and prizes were added for flute-playing, athletic sports, and horse and chariot racing. Eventually contests in tragedy and other kinds of poetry, painting, sculpture, and historical narratives were introduced. At first the prizes were silver or gold, but afterward they consisted of the laurel wreath and the symbolic palm-branch. The statues of

PYTHON (*Python molurus*)

the victors were erected in the Crissæan plain. They continued to be celebrated, it is believed, until the end of the 4th century.

Pythias, pith'î-as. See DAMON AND PHINTIAS.

Pythias, Knights of. See KNIGHTS OF PYTHIAS.

Py'thon, a genus of serpents included in the family *Boidæ*, and the popular name for the same. They form a subfamily (*Pythonidæ*) distinguished from the true boas by having teeth in the premaxillary bone, a pair of supraorbital bones, and the ventral plates of the tail mostly in two rows. With one exception all the pythons belong to the Old World, while the boas occur in both hemispheres. These snakes may possess more than 400 vertebrae, and *P. reticulatus*, of the Malay Islands, and *P. molurus*, of India and Ceylon, may attain a length of 30 feet. A rudimentary pelvis and traces of hinder limbs exist in the pythons, these structures terminating externally in a kind of hooked claw, which, together with the short prehensile tail, adapt them to arboreal habits.

Although destitute of any venomous qualities, these snakes are greatly dreaded on account of their enormous strength. They suspend themselves from the branches of trees, generally in the neighborhood of water, and lie in wait ready to pounce upon animals which come to drink. The body is wound round the victim, which is crushed into a shapeless mass by the powerful constricting folds of the snake. Greatly exaggerated stories of the huge bulk which these serpents are able to swallow have been circulated, but no doubt a goat or sheep can readily be disposed of. The teeth of these serpents are simply conical recurved structures, which, while useless for mastication, will tend to fix and retain the prey in the mouth, and prevent its egress during the movements of swallowing. The jaws may, through the loose and disjointed arrangement of the squamosal and quadrate bones, be very widely separated from the skull, so as to largely increase the size of the mouth from above downward; while the halves of the lower jaw being but loosely connected by elastic ligaments, the cavity of the mouth can thus be greatly enlarged from side to side also. The throat is also exceedingly distensible, and from a consideration of the foregoing points it is easy to conceive how the bodies of even large animals may be slowly and gradually swallowed. The process of deglutition once begun

is largely mechanical. The snake neither sees nor tastes the object, and the mandibles work back and forth alternately to force it down the throat, and largely independently of the snake's will. Thus a number of cases are on record in which blankets, having become entangled in the teeth of large serpents, were reluctantly swallowed and caused their death.

Pythons lay numerous eggs, about which the female coils more to protect than to incubate them. This habit is frequently observed in zoological gardens. The African pythons rarely exceed 12 or 15 feet. Others occur in Australia. The only American representative of the subfamily is *Loxocemus bicolor*, of Mexico and Central America. Consult: Bumpus, 'Standard Natural History,' Vol. III. (Boston, 1885); Boulanger, 'Fauna of British India' (London, 1890). See Boa.

Pyx, anciently any casket and in particular a jewel-case. The present significations of the word are: (1) The vessel, of gold or silver-gilt, in which, in Catholic churches, the blessed sacrament is reserved; called also ciborium; and the small silver-gilt vessel in which the host is carried to the sick for administration at their homes. In former times the pyx had the form of a dove and was suspended above the altar; in present usage it is reserved in the tabernacle or shrine above the high altar. (2) The box or chest in which, at the English mint, specimens of the coinage are deposited, to be tested by a jury of goldsmiths about once in three years; this test is called the "trial of the pyx."

Pyxie. The pyxie, or flowering moss (*Pyxidantha barbata*), is one of the most beautiful and early-flowering plants of the moist, sandy, pine-barren regions of New Jersey and North Carolina. It is found only in certain localities even in this restricted district, but is abundant in its chosen haunts, blooming in April. The pyxie belongs to the *Diapensia* family, very closely related to the heather tribe, and is a small, evergreen, shrubby plant, lying, cushion-like, flat on the sand, and having long, tapering branches trailing in all directions. The small, rigid, pointed leaves are tinged with red at blossoming time, and are very numerous, but are nearly hidden by the profusion of waxen, symmetrical, five-lobed flowers, coral-tinted in the bud, creamy white when open. The twin anther-cells of the five anthers are globose and transversely valved, whence the Greek generic name, meaning box-anther.

Q

Q the seventeenth letter of the English, Latin and other alphabets of western Europe. As in Latin so in English it is always followed by the vowel *u*: as in English so probably in ancient Latin *qu* was equal to *cu* or *kw*: *q* is therefore a superfluous letter and has no place in a scientific alphabet, save as standing for some sound differing from that of *k*: in A. J. Ellis's palæotype alphabet *q* stands for nasal *ng*. Some of the ancient Latin grammarians regarded *Q* as a contracted form of CV (that is *cu*); but others, and with them modern philologists recognize in *Q* a modified form of the koppa of early Greek *Q*, derived from the Phœnician alphabet. This character occurs in very ancient Latin inscriptions; but later the down stroke was written aslant, *Q*, whence the form *Q*. *Q* was not employed in Anglo-Saxon writing, *cw* being used instead: *cwēn*, queen; *cwellan*, to quell; nor was it used in early Teutonic writing, except for words borrowed from Latin; but afterward words of native Germanic origin were spelled with *q*: *quālen*, to torment; *quer*, thwart.

Qua (kwä) **Bird.** See **HERON**.

Quackenbos, kwäk'ën-bös, **George Payn**, American educator: b. New York 4 Sept. 1826; d. New London, N. H., 24 July 1881. He was graduated at Columbia in 1843 and admitted to the bar. Later he abandoned law and for many years conducted a large private school in New York. He published: 'Advanced Course of Rhetoric and Composition' (1854); 'School History of the United States' (1857); 'Natural Philosophy' (1859); and many other once popular text-books.

Quackenbos, **John Duncan**, American physician: son of G. P. Quackenbos (q.v.): b. New York 22 April 1848. He was graduated from Columbia in 1866 and from the College of Physicians and Surgeons in 1871, and has since practised in New York. He became adjunct professor of English at Columbia in 1884, and was professor of rhetoric in Barnard College 1891-3. He is a specialist in mental diseases and has published among various other works, 'History of the World'; 'History of Ancient Literature'; 'Tuberculosis'; 'Typhoid Fever'; 'New England Roads and Roadside Attractions'; 'Hypnotism in Mental and Moral Culture.'

Quackenbush, kwäk'ën büsh, **Stephen Platt**, American naval officer: b. Albany, N. Y., 23 Jan. 1823; d. Washington, D. C., 4 Feb. 1890. He entered the navy as midshipman in 1840, received rank as lieutenant in 1855 and

lieutenant-commander in 1862. In the early part of the Civil War he had charge of the Delaware, Unadilla, Pequot, Patapsco, and Mingo in the blockading squadron, covered Gen. Burnside's army at Aquia Creek and Roanoke Island, participated in the battles at Elizabeth City and New Berne, N. C., engaged the Confederate batteries at Winton, N. C., and destroyed the town. He later took part in the engagements at Sewell's Point landing, Wilcox landing, and Malvern Hill, and received at the last mentioned place a wound from which he lost his right leg. In 1863 he captured the Princess Royal loaded with materials for a Confederate ironclad. In 1864 while dredging Charleston harbor for torpedoes his ship, the Patapsco, was struck by a torpedo and sunk. Later he was in command of the Mingo, protecting Georgetown, S. C. He became rear-admiral in 1884 and was retired in 1885.

Quadi, kwä'dī, an ancient powerful people of southeastern Germany, of the Suevic race. They inhabited the country bounded by Mount Gabreta, the Hercynian forest, the Sarmatian mountains, and the Danube; their neighbors being the Gothini and Osi on the north, the Jazyges Metanastæ on the east, the Pannonians on the south, and the Marcomanni on the west. With the last named people they were on terms of alliance. In the reign of Tiberius the Romans erected a kingdom of the Quadi; but in the reign of Marcus Aurelius the Quadi joined the great German confederacy against the empire, and in 174 were on the point of destroying the imperial legions in a great battle when a sudden storm, attributed to the prayers of the Christian soldiers in the emperor's army, enabled the Romans to recover from their confusion and achieve a complete victory. The independence of the Quadi was recognized by Commodus in 180. They disappear from history about the close of the 4th century.

Quadrages'ima, the period of the 40 days' fast preceding Easter: the season has a like name in Greek, *Tesserakostē*, fortieth. The first Sunday of Lent is sometimes called Quadragesima, but in the Roman calendar it is *Dominica prima Quadragesimæ*, first Sunday of Lent; and the Sundays following are denominated respectively, the second, third, and fourth of Quadragesima, Passion Sunday (*Dominica Passionis*), and Palm Sunday (*Dominica Palmarum*). In the Book of Common Prayer these six Sundays are called the first, second, third, fourth, and fifth of Lent and "Sunday next before Easter"; but this Sunday is also styled in England and the United States "Passion Sunday," and its week "Passion Week"; its familiar name among Catholics is "Holy Week."

QUADRANGLE—QUADRATURE OF THE CIRCLE

Quad'rangle, a square or four-sided court or space surrounded by buildings, as often seen in the buildings of a college. Also in geometry, a figure having four angles, and consequently four sides.

Quadrant. See SURVEYING.

Quadrant Electrometer, in electricity, an instrument constructed by Sir William Thomson (Lord Kelvin) to measure with great accuracy small charges of electricity. See ELECTROMETER.

Quadratè Bone, the squarish bone developed in reptiles and birds, by means of which the lower jaw is articulated or joined to the skull. The lower jaw of these forms is thus not articulated directly or of itself to the skull, as in mammals; and in reptiles and birds each half of the lower jaw is composed of a number of distinct pieces. In mammals, on the contrary, the lower jaw consists simply of two halves united together in front. The *os quadratum*, or quadratè bone, which thus forms a characteristic structure of birds and reptiles, is generally regarded as corresponding in mammals to one of the little bones or auditory ossicles of the internal ear, named the malleus. See EAR.

Quad'rature of the Circle. The problem involved in the quadrature of the circle requires the determination of the length of a straight line such that the square constructed thereon shall have an area equal to that of a given circle. It can be shown in a variety of ways that, if r is the radius of the circle, the area will be equal to πr^2 where π can only be obtained approximately in terms of a finite number of fractions. On the other hand, it has become a matter of general information that the quadrature of the circle is impossible, and this is true only when the ancient Greek problem is understood, which involves a serious limitation; that is, the quadrature must be effected by means of a geometrical construction in which the mathematician is limited to the use of but two instruments, the straight edge and a pair of compasses. The problem is not solved, therefore, if any other instrument or any equivalent analytic method is employed. For four thousand years innumerable attempts have been made to discover this construction, all destined to fail, as it was demonstrated by Lindemann in 1882 to be impossible. In reaching this conclusion we are confronted by the fundamental question: What geometrical constructions are, and what are not, possible, when restricted to the use of these instruments? In analysis, operations correspond to constructions. The operation, $a \times b$, involves taking b units a times, which, with an assumed unit of length, is equivalent to laying off a line having $a \times b$ units of length, which is accomplished by using the method of proportions. In a similar manner, the rational operations of addition, subtraction, multiplication, and division find a geometrical solution involving the straight edge alone.

Irrational operations are divided into algebraic and transcendental. Any operation that involves the extraction of a square root only presents the simplest case of an algebraic irrationality, and any construction involving the determination of the points of intersection of two circles, or a circle and straight line, leads to

an equation of the second, of the fourth, or of some higher degree, whose solution involves the extraction of square roots and rational operations only. Conversely, the necessary and sufficient condition that unknown quantities can be constructed with the straight edge and compasses is that the unknown quantities can be expressed explicitly in terms of the known by an analytic expression involving only a finite number of rational operations and square roots. In other words a Euclidean geometrical solution is impossible when no corresponding algebraic equation exists. When a number like $\sqrt{2}$ is the root of an algebraic equation with integral coefficients, for example, $x^2 - 2 = 0$, and still can not be expressed exactly in terms of a finite series of numbers it is an algebraic irrational number. When the number, like e , the natural base in the theory of logarithms, or π , the ratio of the circumference to the diameter, is not the root of any algebraic equation, with integral coefficients, it is a transcendental number. Lindemann proved that π is a transcendental number and, hence, since it is not the root of any algebraic equation, it can not be constructed to an assumed unit by the extraction of square roots, that is by using the straight edge and compasses.

The possibility of a geometrical solution in general depends upon a theorem in the theory of numbers to the effect that *the degree of the irreducible equation satisfied by an expression composed of square roots only is always a power of 2*; whence, conversely, *if an irreducible equation is not of degree 2^n , it cannot be solved by square roots*.

Next to the squaring of the circle, the most famous problems of antiquity are the *Delian problem* or the *duplication of the cube* and the *trisection of an arbitrary angle*. Granting the preceding general theorem, these are easily shown to be impossible when restricted to the straight edge and compasses.

The duplication of the cube requires the determination of the edge of a cube x , such that its cube shall be twice the volume of a given unit. That is $x^3 = 2$. This equation is irreducible, since otherwise $\sqrt[3]{2}$ would be rational. Moreover, the equation is a cubic and its degree is not of the form 2^n . Hence the solution is in general impossible.

The problem of the trisection of an arbitrary angle corresponds to the solution of

$$x^3 = \cos \phi + \sqrt{-1} \sin \phi,$$

and it follows that in general this is impossible by Euclidean methods.

History.—The quadrature of the circle is attempted in the Rhind Papyrus (2000 B.C.), the oldest known mathematical work, in which Ahmes, an Egyptian priest, lays down the empirical rule: "Cut off one ninth of the diameter; the square on the remainder will equal the area of the circle." This rule affords $\pi = (\frac{16}{9})^2 = 3.16 \dots$, a value reasonably accurate as compared with $\pi = 3$, the value assumed in the Bible (1 Kings vii. 23, Chronicles iv. 2). Archimedes (200 B.C.) invented the method still used by students of plane geometry that depends on inscribing and circumscribing regular polygons, which, save for an improvement by Huygens (1654), remained in use until the invention of the calculus of Newton and Leibnitz (1670-

1770). Hippocrates of Chios (470 B.C.) was the first to investigate areas bounded by curves and to bring into prominence the problems of squaring the circle and duplication of the cube. According to Philoponus, the Athenians were suffering from a severe plague of typhoid fever in 430 B.C., and were told by the oracle at Delos that Apollo required an altar in the form of a cube twice the size of the one existing. A new one was therefore constructed, having each edge twice the length of the old one, but the plague was worse than ever. Suspecting some mystery, confirmed by the insistence of the oracle, the Greeks applied to Plato, the most illustrious of their geometers, and were referred by him to Hippocrates. He succeeded in reducing the problem to the determination of two mean proportionals: for, if $a : x = x : y = y : 2a$, then $x^2 = ay$ and $y^2 = 2ax$, the equations of two parabolas, which intersect in a point whose abscissa is $x^3 = 2a^3$. This is equivalent to a graphical solution by means of conics, but to draw the curves, a different instrument would be required than those prescribed by Euclid. The problem was thereafter known as the Delian problem. The *Cissoid of Diocles* (150 B.C.) and the *Conchoid of Nicomedes* (150 B.C.) are curves of the third and fourth degree respectively, invented for the special purpose of duplicating the cube and trisecting any angle. The curve known as the *quadratrix of Dinostratus* (350 B.C.) which, however, had previously been constructed by Hippias of Elis (420 B.C.) for the trisection of the angle, sufficed also to determine the length of a circular arc and for the quadrature of the circle. It belongs to the class known in modern times as *integral curves*, since the ordinate can be expressed as an integral, such a curve being known to the ancients as a *quadratrix*. If OA and OB are two perpendicular radii of a circle and two points M and L move with constant velocity one upon the radius OB and the other upon arc AB, such that starting from O and A at the same time they both arrive simultaneously at B; then the intersection of OL and MP drawn parallel to OA is a point on the quadratrix. The ordinate, y , is proportional to θ , the angle between OL and OA, and since $y = 1$, when $\theta = \frac{\pi}{2}$, $\theta = \frac{\pi}{2} y$.

But $\theta = \tan^{-1} \frac{y}{x}$, the equation of the quadratrix

$$\frac{y}{x} = \tan \frac{\pi}{2} y.$$

It cuts the axes of X at the point whose abscissa is $x = \lim_{y \rightarrow 0} \frac{y}{\tan \frac{\pi}{2} y} = \frac{2}{\pi}$.

It follows that the radius of the circle is the mean proportional between the length of the quadrant and the abscissa of the intersection of the curve with the axis of X. Hence any apparatus that will describe the quadratrix will enable us to determine π graphically. Evidently the curve $y = \sin^{-1} x$ is much more convenient for this purpose, since π is one of the ordinates of this curve when x equals zero; but this curve does not appear to have been used by the Greeks. It is called the *sinusoid*, the axes being vertical,

and any transcendental apparatus which will trace the sinusoid by continuous motion would afford a geometrical construction of π . Such an apparatus has been invented recently by a Russian engineer, Abdank Abakanowicz, and constructed by Coradi of Zürich. It is called the integrator, and with its aid it is possible not only to lay off π but to trace the *integral curve*.

$Y = F(x) = \int f(x) dx$, when the differential curve $y = f(x)$ is given.

The rise of modern analysis after Newton and Leibnitz developed many new methods for the evolution of π , the best known being the so-called series of Leibnitz,

$$\pi = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \dots$$

After the invention of logarithms by Napier (1614), Euler, by the introduction of complex quantities, developed the celebrated relation between the Napierian base e and π ,

$$e^{i\pi} = \cos \pi + i \sin \pi$$

which for $x = \pi$ reduces to the most remarkable relation in mathematics,

$$e^{i\pi} = -1.$$

The modern proof of the transcendence of π is based upon this relation, since they all depend upon that of e . In 1873 Hermite ('Sur la Fonction exponentielle,' *Comptes rendus*, 1873) first proved the transcendence of e , and this was followed, in 1882, by an analogous demonstration for π , given by Lindemann ('Über die Zahl π ,' *Mathematische Annalen*, XX. 1882). This demonstration is equivalent to proving that the Euclidean problem of the quadrature of the circle is impossible, and closes in this generation a question that has occupied mathematicians for 4,000 years. The long and difficult proofs of Hermite and Lindemann have been much simplified, first by Weierstrass (*Berliner Berichte*, 1885), and in particular by Hilbert, Hurwitz, and Gordon (*Mathematische Annalen*, Vol. XLIII.). The questions involved treated without requiring a knowledge of the calculus have become familiar to English mathematicians through the translation by Beman and Smith of Klein's 'Famous Problems of Elementary Geometry' (1897).

J. BRACE CHITTENDEN, PH.D.,

Professor of Mathematics, Brooklyn Polytechnic Institute.

Quadriennium Utile, kwä-d-rî-ën'-i-üm ü-tî-lâ (Latin, meaning "four years useful"), a phrase in Scotch law, referring to the four years after majority, during which period, a person may set aside or revoke any deed executed during his minority, if such deed is to his prejudice. The same law existed among the Romans, to protect the rights of minors by giving them, after majority, an opportunity to revoke any deed which had been made to their disadvantage, when they were inexperienced minors or, in the eyes of the law, infants.

Quadri'ga. See CHARIOT.

Quadrilat'eral, a common name for the four fortresses of North Italy: Mantua, Legnago, Peschiera, and Verona, which form an outwork to the bastion of the mountains of the Tyrol. They have figured prominently in the

wars between Austria and the different Italian states.

Russia has a combination of four fortresses in Poland, which are called the Polish Quadrilateral.

Quadrilateral. See POLYGON.

Quadrille, kwäd-ril', or kä-dril', (1) a dance of French origin, but now popular in most civilized countries of the globe, and which consists generally of five consecutive figures or dance movements, danced by four couples, each forming the side of a square; or by four sets (often pairs) of couples. (2) Also an obsolete game of cards played by four persons. The game is celebrated by Pope in "The Rape of the Lock."

Quadriscac'ramenta'rian, or Quadriscacramentalist, a term of theological polemic applied by Melancthon and the Lutherans to certain of the Reformers in Wittenberg and its vicinity who maintained the divine institution and necessity for salvation of four sacraments (Latin, *quadri*=*quatuor*, four, *sacramentum*, sacrament), namely, in addition to the two approved by Luther, Baptism and the Eucharist, other two, namely, Confession (or Absolution, or Penance) and Order.

Quadriv'ium, the name given in the Middle Ages to the four mathematical branches of study, arithmetic, music, geometry, and astronomy, in contradistinction to the Trivium, which consisted of the three remaining branches taught in the mediæval schools, and which consisted of grammar, rhetoric, and dialectics, the whole comprehending what was called the seven liberal arts.

Quadroon', or **Quarteroon**, a person of mixed blood, usually one who is one quarter negro and three quarters white; that is, one of whose grandparents was white and the other negro; and one of whose immediate parents was white and the other mulatto.

Quadru'mana, the name applied by Cuvier and others to denote the order of "four-handed" mammalia represented by the lemurs, monkeys, and apes, from the fact that these forms agree in possessing a great toe so constructed as to be capable of opposing the other digits of the feet, instead of being placed parallel with the other toes, thus forming a kind of "hand" adapted for supporting the foot on the ground. Cuvier separated man as a collateral order *Bi-mana* or "two-handed" mammalia. But in modern zoology, man is included in one order with the apes and monkeys — the order *Primates* (q.v.).

Quad'ruple Alliance, a union of four sovereigns or states to forward their common policies. Notable among such unions was the alliance between Great Britain, France, and the German Empire, concluded at London in 1718, in which Holland joined 1719; its objects were to secure to the house of Hanover the succession to the British crown; to secure France to the house of Bourbon; and to prevent the union of France and Spain under one crown. Another memorable quadruple alliance was that of Austria, Russia, Great Britain, and Prussia, formed in 1814 to regulate the political system of Europe after the fall of Napoleon. And in 1834 England, France, Spain, and Portugal entered into

an alliance to put down Don Carlos and his partisans.

Quæstor, kwës'tôr, the title of a class of magistrates in ancient Rome who had charge of the pecuniary affairs of the commonwealth: they were the treasurers of state. Of these one, *quæstor urbanus* or *q. ærarii* (urban quæstor, quæstor of the treasury), who remained at Rome, administered the public revenues and expenditures. Other quæstors, called provincial or military quæstors, served as assistants to the proconsuls or proprætors who governed the several provinces: their duty was to provide for the payment and provisioning of the troops, to collect the imposts, and, in the absence of the governor, to act in his stead. In very early times there was in Rome an official styled *quæstor parricidii* (tracker of murder) who prosecuted persons charged with capital offenses. A quæstor was *ex officio* entitled to a seat in the senate.

Quagga, kwäg'gä, a species of the horse (*Equus quagga*), nearly allied to the zebras, formerly found on the plains of southern Africa, but now quite extinct. It was striped like the zebra, but did not possess bands on the limbs. The color was dark brown on the head, neck, and shoulders, the back and hind quarters being lighter, while the croup was russet gray. The under parts of the body were white, the upper parts of the legs and tail being marked by whitish bars. The quagga was smaller than the zebra, and bore a closer resemblance to the horse. The ears were short, the head being relatively small. The tail was tufted. These animals were gregarious, the herds which inhabited the Kaffrarian plains numbering each several hundreds of individuals, which would mingle with the zebra herds. The quagga was active, nimble, and elegant in its movements. The Bushmen and Kaffirs esteemed the flesh as good palatable food, and these animals were on the same account unremittingly pursued by the lion. It was tamed without much difficulty, but domestication apparently altered its disposition and rendered it dull and less active in habits. The Dutch colonists were said to be in the habit of keeping quaggas along with their cattle; and the quaggas defended the cattle from the attack of hyænas and other carnivora, by trampling on the invaders and otherwise injuring them. The quagga bred with the common horse; and a mixed race of this kind, possessing great beauty of form, and retaining in a great degree the characteristic markings of the quagga, is said to have existed in England at one time. The name "quagga" was derived from the cry of the animal, which may most nearly be expressed by the word *Coua-ag*. The animal has received a variety of names from authors: thus Pennant terms it the *quacha*, and Masson the *opagha*. Consult: Bryden, 'Nature and Sport in South Africa' (1897), and early writers on South Africa, especially Harris, Lichtenstein, and Gordon-Cumming.

Quaglio, kwä'lê-ô, name of a family of painters, originally belonging to Laino, Lago Maggiore, Italy, but afterward dwellers in Munich. The most eminent among them, Domenico (b. Munich 1 Jan. 1786; d. Hohenschwangau 9 April 1837), was for 11 years decorative painter for the Munich Theatre. He subsequently

turned his attention to oil-painting and also executed etchings and lithographs. He traveled through Germany, along the Rhine, to the Netherlands, to France, Switzerland, and Italy, with the object of studying mediæval architecture as a subject for painting. During the latter period of his life he was engaged by the Crown Prince Maximilian of Bavaria in the restoration and decoration of the castle of Hohenchwangau. He was member of the Academy of Munich and Berlin and one of the first German artists to produce in painting architectural effects of a thoroughly artistic quality. He also published books on the mediæval buildings of Bavaria; on the most noteworthy buildings of Munich; and on the architectural statuary of Bavarian mediæval buildings. His brother, LORENZ QUAGLIO (b. Munich 19 Dec. 1793; d. there 15 March 1869), directed his studies to genre painting and lithography. In this latter department of art he reached the highest excellence. His paintings consist of incidents from mediæval life, and his landscapes are taken from the highlands of Bavaria. The third brother, SIMON QUAGLIO (b. Munich 23 Oct. 1795; d. there 8 March 1878), was scene painter and decorator to the Hof Theatre and executed many exceedingly clever pictures in oil, chiefly of architectural subjects and distinguished for faultless perspective, beauty of design, and brilliancy of coloring. ANGELO, son of the last (b. Munich 13 Dec. 1829; d. there 5 Jan. 1890), was scene painter to the Bavarian Hof Theatre, and by his architectural decorations gained a world-wide reputation.

Quaha, the side-striped African jackal (*Canis lateralis*). See JACKAL.

Quahog', or **Round Clam**. See CLAM.

Quai D'Orsay, *kā dōr-sā*. See PARIS.

Quail, one of several partridges (q.v.); in the eastern United States the bob-white (*Colinus virginianus*), and on the Pacific coast partridges of other genera. The eastern bob-white requires no description beyond a statement of the differences between the sexes. Besides being larger, the male has the superciliary line and throat pure white, these parts being buff and without black borders in the female which also has the colors generally more blended. The bob-white is widely distributed throughout the eastern United States; on the Atlantic coast it barely enters Maine, farther west it is found northward in New York, Ontario, and Minnesota; southward it is abundant in the Gulf and South Atlantic States, and westward reaches to the elevated central plains from South Dakota to Texas. Farther westward at many points in this country, in Jamaica, and other West Indian islands this species has been very successfully introduced, but similar attempts in Europe seem to have failed. The Florida and Texan birds present extremes of variation which are considered worthy of recognition as sub-species, and a related species of *Colinus* (*C. ridgwayi*) occurs in Arizona. Although in New England and elsewhere called "quail," and in the Middle and Southern States very generally "partridge," neither of these names is, properly speaking, correct. The bob-white of the farmer's boy is a far more characteristic and appropriate name. Like related species it is gregarious, but the coveys consist of members of one family—a pair of

old birds and their numerous progeny of one or two broods—which remain in company until the next pairing season. They live on partially open land where thickets, woodland borders, or fence rows offer suitable cover. Throughout most of the year they feed upon berries, seeds, and mast, but also frequent the grain-fields, especially after harvest, to glean the fallen seeds. Occasionally they attack fields of buckwheat, of which they are very fond, but the slight damage thus done is repaid many fold in the destruction of grasshoppers and other insects in the late summer and autumn. Most of their life is spent on the ground, on which they scratch like hens. When whistling or sometimes when alarmed they will perch upon trees or fences, but under the latter circumstances they usually run to a cover, where they remain perfectly motionless, or spring suddenly into the air with a loud whirr and fly swiftly straight away to a thicket. At night they commonly huddle together in a close bunch with heads outward in the concealment of a bush, but may occasionally roost on trees. The call is a clear loud whistle of two or three notes, variously interpreted as bob-white, and ah, bob-white; buckwheat and no buckwheat; or more wet, and no more wet, according to the point of view of the listener; the last has reference to the bird's supposed gift of meteorological prophecy.

Being non-migratory, the bob-white is frequently exposed to privation during the winter. During a heavy snow-storm the members of a covey will often huddle together to keep warm and allow themselves to become completely covered. Under ordinary circumstances they find their way out without difficulty, but should a crust form on the surface many will sometimes perish miserably from hunger, cold, and lack of air. In April and May they construct simple nests of coarse grass stems, usually arched over at the top, in a depression on the ground under the shelter of a bush or tuft of grass. The eggs are pure white and top-shaped. Numerous eggs—from 16 to 32—are found in each nest, and are very neatly arranged with the pointed ends downward. Whether they are the product of one or of several females is a matter of dispute, but certain it is the bob-white is typically monogamous, though occasionally he may take two wives. The young run immediately after hatching, and are wonderfully interesting and pretty creatures with a marvelous skill for concealing themselves when alarmed. Sometimes a second brood is raised in August. When this is the case the male takes sole charge of the first until the second is hatched, when both parents join the combined broods; thus are formed the largest coveys.

The bob-white combines all of those qualities which a sportsman seeks in an ideal game bird and it is, without question, the most sought and most generally appreciated by gunners of any game bird in this country. Every condition unites to make the sport exhilarating and healthful, to test the skill of the sportsman, and to please his appetite at the close of his labors. In most States this perfect game bird is now rigidly protected by laws prohibiting snaring, netting, and trapping, by the enactment of a close season covering the breeding period and continuing until the young birds are strong of wing, by prohibiting, under penalty of a heavy fine,

the shipment of birds outside of the State's jurisdiction, by requiring the payment of a license fee by non-resident shooters, or by other measures designed to meet local conditions or abuses. Although the bird is so prolific it has numerous natural enemies, especially hawks, weasels, skunks, cats, etc., which check its increase. When to this natural loss is added the enormous number annually sacrificed to the deservedly popular sport of quail-shooting, the necessity of legal protection becomes manifest. The nature and method of the sport differs so much with the varied actions of the birds due to season, locality, character of ground, etc., and to the local and personal idiosyncrasies of gunners, that the reader must be referred to some of the numerous sporting books for details. The general method is to hunt singly or in couples, with one or two dogs, which quarter the ground under the guidance of signs and whistled signals from the sportsman. When the birds flush they spring up suddenly and immediately attain full speed, which keeps the gunners always on the *qui vive*. Either pointer or setters may be used according to the character of the ground and the personal preference of the sportsman. By many the Llewellyn setter is considered to be the most perfect dog for rapid quartering of the ground and general adaptation to this class of sport. As to guns tastes differ; but a first-class, hammerless arm of moderate weight, long range, and 12 or 14 bore has the preference of experts. Smokeless powder is highly recommended.

J. PERCY MOORE,
University of Pennsylvania.

Quain, kwān, **Jones**, English physician: b. Mallow, Ireland, 1796; d. London 27 Jan. 1865. He studied medicine at Dublin and Paris, and was professor of anatomy and physiology at London University 1831-6. He was the author of *Quain's 'Elements of Anatomy'* (1828, 10th ed. 1890); and published also a series of 'Anatomical Plates' (1858), and a translation of Martinet's 'Pathology' (1835).

Quain, Richard, English anatomist, brother of J. Quain (q.v.): b. Fermoy, Ireland, July 1800; d. London 14 Sept. 1887. He was appointed professor of anatomy and clinical surgery in University College, London, in 1837, and was elected president of the Royal College of Surgeons in 1868. Among his works are: 'Anatomy of Arteries,' with folio plates (1845); 'Diseases of the Rectum' (1854); 'Observations on Medical Education' (1865); 'Some Defects of Medical Education' (1870). He bequeathed nearly \$375,000 to University College, London, for the "education in modern languages (especially English) and in natural science."

Quain, Sir Richard, English physician, cousin of J. and R. Quain (q.v.): b. Mallow, County Cork, 30 Oct. 1816; d. London 13 March 1898. He studied medicine in University College, London, whence he was graduated in 1842. He was elected a member of the Royal College of Physicians in 1846; in 1871 was chosen a fellow of the Royal Society, and he was president of the General Medical Council from 1891 till his death. His practice in London was large and lucrative, and besides publishing several medical treatises he edited a well-

known 'Dictionary of Medicine' (1882; new ed. 1894).

Quaker City, a popular nickname applied to Philadelphia, which was planned and colonized by William Penn and other members of the Society of Friends.

Quaker Hill, Battle of, in the American Revolution, a notable battle fought 29 Aug. 1778. On the previous night, the 28th, the Americans on Rhode Island fell back toward Butts Hill at the northern end of the island. Contrary to Greene's advice the enemy were allowed to occupy Quaker and Turkey Hills. From these hills the British assailed the Americans, but were repulsed and driven back to Turkey Hill. The hottest of the battle took place on the low ground between the hills. The American loss in killed and wounded was 206; that of the British 222.

Quaker Ladies, or Quaker Bonnets. See HOUSTONIA.

Quaker Poet, The, a name often applied to John Greenleaf Whittier, and long before his day bestowed upon the English poet, Bernard Barton (q.v.).

Quakers. See FRIENDS, RELIGIOUS SOCIETY OF.

Quality, in the language of logicians, is used to designate the nature of propositions as affirmative or negative; the proposition "gold is a yellow substance" is of affirmative quality; "gold is not easily fusible" is a proposition of negative quality. In metaphysics quality is either primary or secondary: primary qualities are those which are essential to the existence, or even the conception, of the thing; secondary qualities are those not essential to such conception: whether primary or secondary, a Quality is that which makes, or helps to make, anything such as it is.

Qua'na, Comanche chief: b. about 1845. He is the most influential chief among the three confederated tribes of Kiowa, Comanche, and Apache in southwestern Oklahoma, and is a half-breed, his mother being a white captive married to a Kwahadi chief. Quana became prominent in 1874, when he acted as leader of the band of 700 picked warriors from the confederated tribes in an attack on the South Canadian River fort, Adobe Walls. He was active in the Indian uprisings of the following year, and was the last to surrender when peace was ultimately made. His superior intelligence, however, induced him to acquire white habits and customs, and after some time spent in Texas he became thoroughly convinced of the benefits of civilized life and on his return to his tribe endeavored to persuade them to adopt his views. In 1882 he proposed leasing the surplus pasture lands of the reservation, a measure which increased the income of the tribes by \$100,000 yearly. In 1888 he was appointed a judge of the Indian court, and in 1892 was the first signer of the treaty which opened the reservation lands to settlers in 1901.

Quantification of the Predicate, supplying to the predicate in a logical proposition a word, as "some," or "all," or "no," etc., to indicate whether the whole of it or only a part agrees with or differs from the subject. In the proposition "all metals are elements" the subject "metals" is quantified by the use of "all";

but the predicate is not quantified, and in form the proposition does not distinctly assert whether metals constitute the whole list of elements or not. But by inserting "some" before the predicate, "elements" is quantified—"all metals are some elements." It was assumed by Aristotle and was maintained by all logicians after him till Ploucquet and Lambert in the 18th century and Sir William Hamilton in the 19th, that the predicate of all affirmative propositions is "undistributed" (not taken in its universal comprehension), while the predicate of a negative proposition is always distributed. But, after Sir William Hamilton had given notoriety to the doctrine of quantification, this was seen to be an error, through which an infinite number of affirmative propositions which are universal in both terms are excluded from the system of formal logic. Among the numerous changes in the theory of formal logic which follow from the adoption of the quantified predicate the most important are the reduction of the conversion of propositions from three species to one, reduction of all the general laws of categorical syllogisms to a single canon, and the abrogation of all the special laws of syllogism. But the doctrine of the quantification of the predicate has never been generally adopted in the exposition of formal logic, on the ground that there is no proposition that cannot be dealt with under the Aristotelian forms, and that quantification does not really simplify the theory of logic.

Quantity, in the language of *Mathematics*, is whatever can be increased or diminished or measured: space, time, weight, number, force, etc., are quantities. Quantities are represented in mathematics by symbols, and these too are called quantities. In algebra quantities are distinguished as known and unknown, real and imaginary, constant and variable, rational and irrational: a real quantity is one not involving an impossible operation; variable quantities are those which admit an infinite number of values in the same expression; rational, those which do not involve any radicals. A simple quantity is expressed by a single term, as a or b ; a compound quantity is one expressed by two or more terms connected by the sign of plus (+) or minus (—). Quantities having the plus sign prefixed are called positive or affirmative: those with the minus sign prefixed are called negative quantities. Similar quantities are such as consist of the same letters, and the same powers of the letters, as abc , $-2abc$, $+4abc$, etc. In *Logic*, quantity is the extent to which the predicate in a proposition is asserted of the subject: when the predicate is affirmed of the whole of the subject the proposition is a universal one, as in the example "all metals are elements": but when the predicate is affirmed only of a part of the subject, as in "some metals are brittle," the proposition is called a particular one. In *Grammar* and *Prosody*, quantity is the measure of a syllable, or the time in which it is pronounced. In *Music*, quantity is the relative duration of a tone.

Quantiv'alance. See VALENCY.

Quan'trell, William. American guerrilla: d. Kentucky, 1864. His depredations first became widely known when he raided Lawrence, Kan., destroying 185 buildings, killing 140 inhabitants and leaving the town completely

devastated. His operations were then continued through western Missouri and eastern Kansas, but upon his extending his ravages to Kentucky, in 1864 he was outwitted and killed.

Quan'za, a river of Africa. See KWANZA.

Quapaw (kwá'pá) Indians. See SIOUAN.

Quarantine, a stated period (formerly 40 days) during which a ship coming from a port suspected of contagion, or having a contagious sickness on board, is forbidden intercourse with the place at which it arrives. Quarantine was first introduced at Venice in the 14th century. It is now required to be performed in almost every important country except Great Britain. In the United States quarantine enactments were passed by the colonial legislatures and afterward for many years by the States. The first national quarantine act was passed 23 Feb. 1799, requiring Federal officers to aid in the execution of State or municipal quarantine regulations. On 29 April 1878, a national quarantine act was passed. On 3 March 1883, \$100,000 was appropriated for maintaining quarantine points along the coast. On 1 Sept. 1892, owing to the presence of cholera, President Harrison proclaimed a 20 days' quarantine of New York. By law it is made a misdemeanor punishable by fine or imprisonment, or both, for the master, pilot, or owner of any vessel entering a port of the United States in violation of the act, or regulations framed under it. During the period of quarantine, all the goods, clothing, etc., that might be supposed capable of retaining infection, are subjected to a process of disinfection, which is a most important part of the quarantine system.

From 7 Nov. 1896, the system of quarantine ceased to exist in Great Britain, so far as regards the British Islands. The Quarantine Act of 1825 required that quarantine should be performed by vessels coming to the British Islands from places from which "the plague or other infectious disease or distemper highly dangerous to the health of his Majesty's subjects" might be brought; but in recent years this act has applied only to the plague and yellow fever, and has not often been used. Vessels arriving from infected places or carrying goods, etc., from such places, were required to be kept at some safe distance from the shore and from other ships—all their passengers and crew being detained on board—till all danger of spreading infection was considered to have passed. Healthy persons were thus exposed to the risk of taking any disease there might be on the ship.

In some places quarantine establishments were maintained for receiving persons from suspected vessels, but most of these were long since abolished, and latterly the only such receiving ships were some old hulks at the Motherbank in the Solent. These were maintained by the Privy Council, on whom devolved the administration of the Quarantine Acts. Orders in Council prescribed the system of quarantine. By the Public Health Act of 1875, the defense of the country against cholera was placed in the hands of the Local Government Board, and regulations were issued by that board for the purpose. Instead of quarantining the entire crew of an infected or suspected vessel, the method adopted consisted in the medical inspection of the persons on board, and the separation and detention of those who were suffering from cholera or who were sus-

pected of being affected. All others were permitted to leave the ship, but were traced and watched by the local authorities. Infected articles on board were to be disinfected or destroyed.

Quarantine has long been considered ineffective against the introduction of disease, besides being a source of much danger to those who were compulsorily detained under the system. The sanitary ideas of our day favor the less showy but safer methods long used in England in case of cholera.

In the United States under the law of 28 March 1890, known as the Interstate Quarantine Act, the supervising surgeon-general of the Marine Hospital Service is charged with preparing the rules and regulations, under direction of the Secretary of the Treasury, necessary to prevent the introduction of certain contagious diseases from one State to another, and he has also supervision of the medical inspection of alien immigrants, which, under the law of 3 March 1891, is conducted by the medical officers of the Marine Hospital Service. Under the act of 15 Feb. 1893, he is charged with the framing of regulations for the prevention of the introduction of contagious diseases and the prevention of their spread; and he is also charged with the conduct of the quarantine service of the United States. He has the direction of laboratories established to investigate the cause of contagious diseases, and publishes each week, under the title of 'Public Health Reports,' sanitary reports received from all parts of the United States and (through the State Department) from all foreign countries.

Quaritch, kwär'ich, **Bernard**, English bookseller: b. Worbis, Prussian Saxony, 23 April 1819; d. Hampstead, Middlesex, 17 Dec. 1899. In 1839-42 he was employed in a publishing house in Berlin, and in 1846 established himself in London. He was naturalized as a British subject in 1847, and in that year issued his first book catalogue, a single leaf. In 1848 he began issuing a monthly catalogue, which in 1854-64 was printed as a regular periodical under the title 'The Museum.' His business increased rapidly and he became known as an authority on rare and valuable books of all classes. For 30 years he practically controlled the rare book market, attending in person or by proxy every important book auction in England and America. His catalogues are remarkable productions, the first large one being published under the title 'Bibliotheca Xylographica, Typographica, et Palæographica' (1873) and afterward re-issued from time to time with valuable additions, the last complete catalogue being the 'General Catalogue of Old Books and Manuscripts' (1887-8, index 1892, 7 vols.) and increased by supplements in 1894 and 1897.

Quarles, kwärlz, **Francis**, English poet: b. near Romford, Essex, 1592; d. London 8 Sept. 1644. He was educated at Cambridge and before 1629 went to Dublin as private secretary to Archbishop Ussher. In 1639 he was appointed chronologer to the city of London and at the opening of the civil wars wrote a work entitled 'The Loyal Convert.' Of the works of Quarles, in prose and verse, the most celebrated is his 'Divine Emblems,' a set of de-

signs illustrated by verses. A great part of them are borrowed from the 'Emblems' of Hermanus Hugo, but the verses are his own. His 'Enchiridion of Meditations' (1641) is a collection of brief essays and aphorisms, in vigorous and occasionally eloquent language.

Quarrying. Although there are at this time in the United States about 6,000 quarries in operation, with an annual product, valued at \$75,000,000, the quarrying industry has not kept pace with modern tendency and progress toward cheaper production. In building operations revolutionary changes have come about in the last few years in the erection of steel buildings and the manufacture of terra cotta and clay products, while quarrying has been, generally speaking, stationary. The natural result of this has been a large increase in the use of those materials for general bridge and building work, where the natural preference would have been for stone as an ideal and more permanent material, but for its prohibitive cost. As the rapid increase in the use of these other building materials is the direct result of the use of modern methods and machinery to the elimination of hand labor in the greatest degree, it follows that in this direction also lies the continued prosperity of the stone business. As a compromise between the minute subdivisions desired by scientists and the extremely general and often erroneous classification of quarrymen, the following division may be adopted for quarrying operations:

Limestones and Dolomites.—The sedimentary and bedded rocks, composed essentially of lime carbonate, or the mixed carbonates of lime and magnesia. Such have been found to pass into each other by insensible gradations, certain quarries producing at the same time material which, if classed on purely chemical grounds, would be relegated to both divisions.

Marble.—Including stones identical in composition with those noted under limestones and dolomites, but which through changes, mainly physical, have come to possess properties rendering them desirable for high-grade building or ornamental work. The marbles of New York, recently brought to light by The Adirondack Lumber and Mineral Corporation, for instance, are largely limestone, while those in Massachusetts, Berkshire County, are largely dolomite. With the marbles are also included a small series of serpentine rocks, which are likewise utilized for decorative purposes.

Sandstones and Quartzites.—Rocks composed essentially of consolidated sands, being made over, as it were, from the detritus of preexisting rocks. Those classed as *quartzites* are sandstones which have been rendered more or less crystalline through the deposition of silica between the original sand particles, as in the case with the *jasper* of Sioux Falls, South Dakota, or the Potsdam sandstone of St. Lawrence County, New York. The tuffs and other volcanic fragmental rocks are also here included.

Silica Sand.—Silica or siliceous sand includes not only sand suitable for the manufacture of glass, but also a large quantity designated as engine and furnace sand. It exists in several states as a sandstone, requiring crushing and screening; as a stone that

QUARRYING

readily disintegrates when exposed to the action of the elements, and needs only washing or burning to reduce the amount of organic matter and other impurities.

Siliceous Crystalline Rocks.—Here are included the true granites and syenites, together with trappeau rocks, such as are often designated as black granites; the gneisses or so-called striped or bastard granites; the mica schists; and melaphyre, basalt, andesite, syenite, elaeolite, diabase, gabbro, diorite, and other volcanic rocks.

Slate.—Including argillaceous rocks, which, through the process of shearing and incidental chemical activity, have undergone a partial metamorphism, resulting in the development of a pronounced tendency to split along certain planes, which may or may not be parallel with the original bedding, into thin sheets suitable for roofing purposes. It is necessarily a consequence that such are restricted to the regions of pronounced earth movements, such as have resulted in the formation of mountain ranges.

The possible resources of the various States of the Union are as follows:

| State or Territory. | Present and Prospective Resources. |
|------------------------|---|
| Alabama | Granite, Limestone, Marble, Sandstone, Slate. |
| Arizona | Dolomite, Granite, Onyx, Marble Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Arkansas | Elaeolite, Syenite, Granite, Limestone, Marble, Sandstone, Slate. |
| California | Granite, Limestone, Marble, Sandstone, Slate, Trappeau Rocks, Verd Antique Marble, Volcanic Rocks, and Tuffs. |
| Colorado | Granite, Limestone, Marble, Quartzite, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Connecticut | Diabase, Gneiss, Granite, Limestone, Marble, Sandstone, Verd Antique Marble. |
| Delaware | Gabbro, Gneiss, Limestone, Quartzite, Serpentine. |
| Florida | Limestone (shell and oolitic). |
| Georgia | Gneiss, Granite, Limestone, Marble, Sandstone, Slate, Verd Antique Marble. |
| Idaho | Dolomite, Granite, Limestone, Marble, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Illinois | Dolomite, Limestone, Sandstone. |
| Indian Territory | Dolomite, Granite, Sandstone, Limestone. |
| Indiana | Dolomite, Limestone, Sandstone. |
| Iowa | Dolomite, Limestone, Sandstone. |
| Kansas | Dolomite, Limestone, Sandstone. |
| Kentucky | Dolomite, Limestone, Sandstone. |
| Louisiana | Limestone, Sandstone. |
| Maine | Gneiss, Granite, Limestone, Sandstone, Slate, Trappeau Rocks, Verd Antique Marble. |
| Maryland | Gneiss, Granite, Limestone, Marble, Sandstone, Slate, Verd Antique Marble. |
| Massachusetts | Gneiss, Granite, Limestone, Marble, Sandstone, Slate, Trappeau Rocks, Verd Antique Marble. |
| Michigan | Dolomite, Gneiss, Granite, Limestone, Sandstone, Slate. |
| Minnesota | Dolomite, Gneiss, Granite, Limestone, Quartzite, Sandstone, Slate. |
| Mississippi | Limestone, Sandstone. |
| Missouri | Diabase, Dolomite, Granite, Limestone, Sandstone. |
| Montana | Dolomite, Gneiss, Granite, Limestone, Marble, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Nebraska | Dolomite, Sandstone, Limestone. |
| Nevada | Dolomite, Granite, Limestone, Marble, Sandstone, Slate, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| New Hampshire | Gneiss, Granite, Limestone, Slate. |
| New Jersey | Diabase, Dolomite, Gneiss, Granite, Limestone, Marble, Sandstone, Slate, |

| State or Territory. | Present and Prospective Resources. |
|----------------------|--|
| New Mexico | Granite, Limestone, Marble, Sandstone, Trappeau Rocks, Verd Antique Marble, Volcanic Rocks, and Tuffs. |
| New York | Dolomite, Gneiss, Granite, Limestone, Marble, Norite, Sandstone, Slate, Trappeau Rocks, Verd Antique Marble. |
| North Carolina | Dolomite, Gneiss, Granite, Limestone, Marble, Sandstone, Serpentine, Slate, Trappeau Rocks. |
| North Dakota | Dolomite, Sandstone, Limestone. |
| Ohio | Dolomite, Sandstone, Limestone. |
| Oklahoma | Dolomite, Granite, Limestone, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Oregon | Dolomite, Granite, Limestone, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Pennsylvania | Diabase, Dolomite, Gneiss, Granite, Limestone, Marble, Sandstone, Slate, Serpentine. |
| Rhode Island | Dolomite, Gneiss, Granite, Limestone. |
| South Carolina | Gneiss, Granite, Limestone. |
| South Dakota | Limestone, Quartzite, Sandstone. |
| Tennessee | Granite, Limestone, Marble, Sandstone, Slate. |
| Texas | Granite, Limestone, Marble, Sandstone, Slate, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Utah | Granite, Limestone, Marble, Onyx, Marble, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |
| Vermont | Dolomite, Gneiss, Granite, Limestone, Marble, Slate, Verd Antique Marble. |
| Virginia | Diabase, Dolomite, Gneiss, Granite, Limestone, Marble, Sandstone, Slate. |
| Washington | Granite, Limestone, Marble, Sandstone, Trappeau Rocks, Verd Antique Marble, Volcanic Rocks, and Tuffs. |
| West Virginia | Calcareous Tufa, Limestone, Sandstone, Travertine. |
| Wisconsin | Dolomite, Gneiss, Granite, Limestone, Sandstone. |
| Wyoming | Granite, Limestone, Marble, Sandstone, Trappeau Rocks, Volcanic Rocks, and Tuffs. |

In the earlier days of the stone industry hand methods were employed almost exclusively in the work of quarrying and dressing. The past twenty-five years has, however, witnessed the introduction of machinery and consequent changes. The old method of drilling and blasting, formerly applied to all classes of rocks, is now done away with, excepting in the very hardest and toughest of materials, or where, as in the case of the trappeau rocks, the material is to be utilized only for roads. Even where drilling and blasting are now resorted to, it is the custom to drill a series of holes in the line along which it is desired the stone shall break; these holes are then charged somewhat lightly and fired simultaneously. In this way the force of the explosion is delivered along a considerable surface and the danger of shattering the material through the sudden jar is reduced to a minimum. This process is at present largely limited to granite rocks which are too hard to be quarried by means of channeling machines.

Plug and Feather Work.—In quarries where good breaks require that the splitting strain be exerted well down in the ledge, experience has shown that the best method for getting out the material is usually the *plug and feather* system, in which a series of holes from 1¼ to 2 inches in diameter and of a depth from 2-3 to the full thickness of the sheet are drilled at intervals depending upon the character of the stone and its manner of cleavage. Long metal wedges or plugs are then driven into these holes and the material split away in fairly regular blocks which must otherwise be cut to size by hand.

A MARBLE QUARRY AND PLANT AT PROCTOR, VERMONT.

QUARRYING

In soft material such as sandstone, a drill mounted on the usual tripod finds frequent use, and this is far superior to hand methods, still in certain classes of work a drill mounted on quarry bar will do much more and better work. The advantages of the quarry bar are that all the holes are drilled to double length, intermediate ones being shallow. The lower half of the deep holes is drilled with a smaller drill bit so as to alternate the plug strain top and bottom and control the break by skillful sledging.

The wedges of the short hole tend to split along the top and those of the long hole split along the bottom, thus distributing the pressure and tending to split the stone in a clean, smooth plane, and largely avoiding any tendency to run off. This distribution of splitting strains is to be worked out by experience in the peculiarities of the different ledges. The wedges or plugs need not in all cases be of a length equal to the depth of the holes. In some marble quarries, plug holes only 5-8 inch in diameter are put clear through the blocks, sometimes to feet deep, to weaken the line and insure a straight break, the plugs, however, being shorter.

Broaching.—In granite and other hard stones holes must be placed closer together and, as a rule, splitting across the grain is abandoned in favor of *broaching*. In this system, a series of holes is drilled, usually about 3 inches apart from center to center, depending upon the hardness of the rock, and a flat bit or "broach" is substituted for the regular steel. This has a face about 3-4 by 3 inches, and is forged with a blunt end to crush this thin wall or web between the holes. Drills used for broaching must have the release rotation, which is a simple device to throw the pawls out of action and allow the drill to work without rotating. Broach channeling is the best and cheapest method of cutting out key blocks, lumps, and making wall cuts, etc., in granite quarries, where the rock is too hard to be cut advantageously with the regular channeling machine.

Channeling Machines.—Channeling machines are utilized in the case of rocks of the nature of marble, limestone, and the softer sandstone, since they would be liable to injury through blasting and since it is desired to remove the materials from the quarry bed with a minimum amount of waste and in such size and shape that they may be cut into suitable dimensions. The Wardwell channeling machine, the earliest in use, has given way to the direct-acting stone channeling machine, the design of which was based upon the conviction that the same principles which had made the Ingersoll-Sergeant drill famous, would, properly applied, give the best results in cutting a channel. It was believed that the direct-acting machine possessed points of decided advantage over the slow, cumbersome diamond and lever types of rock-cutting machinery of that day. Although certain shortcomings appeared in the first models, still it is an interesting fact that some of these first machines are in service today after more than fifteen years of continuous use and are still doing good work. The success of these pioneer types demonstrated beyond question the merit of the direct-acting principle now everywhere conceded as the correct one and it remained only to develop to the utmost the details of mechanical construction.

This machine is primarily suited for the

heaviest work and the deepest cuts, in open quarries of limestone, sandstone, slate, and other materials, where the output is in dimension stone. In this service it has found its greatest field in making the long, deep, longitudinal cuts which are preliminary to further breaking by the plug and feather method. It has found another valuable field of application in certain classes of heavy contracting work, such as canals and reservoirs. The advantage of the track channeling machine in this work is threefold; first, the limits of excavation can be distinctly marked by channeling along the limiting line and shooting out within this mark; second, the quantity of rock to be broken and removed is confined strictly to the limits of cut—an item often of great consequence when competition is keen and prices low; third, the walls of the excavation are left smooth and solid, requiring the minimum of attention and maintenance. A notable instance of this canal work was seen in the Chicago Drainage Canal, where more than thirty track channelers of an earlier type were employed. The machines were also used in certain work in the enlargement of the Erie Canal and their performance was eminently satisfactory.

The average cut with these channeling machines is from eight to sixteen feet in depth, depending upon the nature of the stone. The gauge or width of the cut will depend upon the final depth sought. It may be from one and one-half to four inches at the start reducing to a width of one and one-eighth inches with the last steels. The length of the channel is limited only by the length of track which can be used. Cutting speeds vary with the quality of rock and the handling of the machine. There are cases on record where the machine channeled 700 square feet in ten hours in volcanic limestone, during part of which time over 100 square feet per hour was cut. In Ohio sandstone of medium hardness, 260, 280 and 300 square feet per day of ten hours have been channeled and these rates are being maintained as an average by the month. The average cost in this case runs from two and one-half cents to three and one-half cents per square foot cut. On the Chicago Canal the cost was fifteen cents per square foot.

Helicoidal Saws.—Recent attempts have been made to introduce the so-called helicoidal saw for quarrying the softer rocks, as limestone and marble, but with only partial success and that in the larger limestone quarries of the Middle West, owing apparently to the large amount of labor necessary for putting the saw in position and the waste involved in cutting out the corners in which the pulleys are run. The saw, as is well known, consists of a twisted iron-wire rope, generally three-sixteenths of an inch in diameter, running over sliding pulleys, the abrading material being either sand or chilled iron, as the case may be.

After the stone is removed from the quarry bed it is worked into the desired shape and size by a process dependent largely upon the hardness of the stone. Formerly a block after being reduced to an approximately rectangular form by means of hand *plug and feather* splitting, was still further reduced by pitching tools, followed when necessary by such implements as the point, ax, pean hammer, and bushhammer. Pneumatic tools are gradually replacing these hand implements. Pneumatic surfacing machines, lathes

QUART — QUARTER-SESSIONS

and planers are now in use at the larger quarries. Indeed, the production of cylindrical columns by the old hand method has been almost entirely superseded by the use of lathes similar to those used in turning metals. Except on the harder stone, like granite and quartzite, saws are extensively used for splitting up material into rectangular masses and slabs where smooth, even surfaces are desired.

Electricity in Quarrying.—The quarrying industry today constitutes an important field for the application of electric current, and the subject has become so important as to create a literature and a technology of its own, for many of the problems involved are such as do not arise in connection with other work. The flexibility of electric circuits and the general adaptability of electric power have led to a wide range of applications, some of which are still in the experimental stage. Motors and other necessary equipment have been designed for special requirements. Beginning with a small direct current station and leading up to a complete high tension transmission and converting system, the use of electricity in mining and quarrying is very similar to its application to street railway work. Special motors for the equipment of mine locomotives have been designed to meet the peculiar conditions confronted in mining and quarry work. A recent application is that of the gathering locomotive which is to a great extent replacing animal haulage completely. This locomotive is equipped with a reel and cable, supplying power to it when gathering cars from rooms where no trolley is installed and where wooden rails are used. Standard motors are applicable to and are largely used on hoists, ventilating fans and drainage pumps.

The transmission of power over long distances by polyphase alternating current is one of the most notable and important developments in electricity. It has been a chief factor in the marvelous development of the far west. Much of the progress in the country west of the Rockies is directly traceable to the use of electricity which, in many cases, generated at a distant waterfall, is transmitted to commercial centers where the power can be used as desired.

In a typical quarrying operation 100 men were formerly required to produce 5,000 tons of marble; now, since scrapping most of the plant and substituting modern machinery, 10 men produce 6000 tons in the same time. The argument has been presented in all sincerity, that mechanical methods cannot be used to the same advantage in quarrying rock as in the case of general manufacturing. To some extent this is true, depending upon the class of quarrying; for instance, in some quarries producing rough rubble without regard to size or dimensions, the mechanical features are confined to drilling, electrical blasting and suitable hoisting apparatus and perhaps pumping or crushing, with the occasional use of steam shovels. There can be no question as to the economy of machine drilling over hand drilling, and the harder the material and the more difficult to drill by hand, the greater is the advantage of machine drilling.

Successful quarries are those which closely approach the ideal of eliminating hand labor and, as in other profitable operations, are the result of heavy investments in all the machinery

which can be used up to that point where additional apparatus will not reduce the waste. The modern methods of clanneling, plug and feather work, power wedge hole cutters and the use of compressed air, very nearly reach this point as it calls for few machine operators, a few men to bar out the stone so loosened, and a gang of derrick men to place it on the cars for shipment in that attractive form best calculated to hold and expand the market at the highest trade price for the product. In most quarries, the operating period is limited by the comparative shortness of the working season, and therein lies another advantage of machinery. Again, the smaller the force, the more easily it is controlled and the better the opportunity for sifting the men down to a picked gang of machine runners, men who, at a slight addition over the prevailing rate of wages, will not only do very much more work, but will come nearer to the production of a perfect output without wastage.

There exists in the stone industry the same tendency toward the concentration of capital and the formation of stock companies as in other branches of trade. This is due not altogether to the desire for combination with a view to controlling trade, but in part at least to a change which has taken place in the character of the industry. The installation of costly machinery and the fact that the quarries in many cases now contract not merely to furnish the stone, but to furnish it cut and ready for its definite position in the structure, even if they do not contract to set it in place as well, involve a larger capitalization and supply of available funds. See MINES AND MINING; MINING AND MILLING MACHINERY; BUILDING MATERIALS; ETC.

EDWARD S. FARROW,
Consulting Mining Engineer.

Quart. See WEIGHTS AND MEASURES.

Quarter. See WEIGHTS AND MEASURES.

Quarter-crack. See SANDCRACK.

Quarter Days, the days which begin the four quarters of the year, namely: 25 March, or Lady-day; 24 June, or Midsummer-day; 29 September, or Michaelmas-day; and 25 December, or Christmas-day. In England and Ireland it is usually contracted between landlord and tenant that rent should be paid, and that houses may be entered or left on these days. In Scotland there are two legal term days, Whitsunday (15 May) and Martinmas (11 November). There are also two conventional terms, Candlemas (2 February) and Lammas (1 August), on which rents are frequently paid. In the United States, in law, quarter days are the 1st of January, April, July, and October. In the relation between landlord and tenant in some of the States they are the 1st of May, August, November, and February, respectively.

Quarter Dollar, in American coinage, a silver piece of the value of 25 cents. Its issue was first authorized (weight, 104 grains) by Congress in 1792, and its coinage was begun in 1796. It was reduced to 93 grains in 1853. This coin is legal tender to the amount of \$10. There were no issues of the quarter dollar during the years 1798 to 1803, inclusive, 1808 to 1815 inclusive, 1817, 1824, 1826 and 1830.

Quarter Sessions. See COURT.

QUARTER-STAFF—QUARTZ

Quarter-staff, an old English weapon formed of a stout pole of heavy wood, about six feet long, loaded with iron at both ends.

Quartering Acts, acts of the British Parliament which did away with certain of the penalties of high treason as prescribed by law in ancient times. The offender, if a man, was drawn on a hurdle to the place of execution, there hanged by the neck till he was dead, the head severed from the body, the body disemboweled and divided into four quarters, and the head disposed of at the pleasure of the king. If the offender was a woman she was drawn to the place of execution and there burned alive. By successive acts of the parliament (30 Geo. III. ch. 48, and 54 Geo. II. ch. 146) the punishment of a female traitor was changed to hanging; and, in the case of men, the crown might change the sentence to beheading, or might remit it wholly. Under the felony act of 1870 hanging is made the one penalty of treason; but as the act 54 Geo. III. ch. 146 was not repealed, the offender, if a man, may by crown warrant be beheaded.

Quartermaster, (1) in military affairs, an officer who superintends the issue of stores, food, and clothing, and arranges transportation for a regiment when necessary. (2) In nautical affairs, a petty officer who, besides having charge of the stowage of ballast and provisions, coiling of ropes, etc., attends to the steering of the ship. He is appointed by the captain.

Quartermaster-general, in the army of the United States, a staff-officer with rank of brigadier-general. He is chief officer in the quartermaster's department. In England he is a staff-officer, specially appointed for duties connected with quartering, encamping, embarking, and moving troops. In both armies in the field he is responsible for the surveys and reconnaissance necessary for the conduct of the army, and has the general direction of the railway, postal, signaling, and telegraph services.

Quartermaster-sergeant, in the United States army, an officer whose duty it is to assist the quartermaster. In England the senior sergeant in the quartermaster's department of a regiment. He ranks next the sergeant-major.

Quar'tern. See WEIGHTS AND MEASURES.

Quar'teroon'. See QUADROON.

Quartet', or **Quartette** (Italian *quartetto* from *quarto*, a fourth), a musical composition for four voices or instruments, in which all the parts are *obbligati*, that is to say, each is indispensable to the just performance of the piece; no one part can be omitted without injuring the proper effect of the composition. Vocal quartets are generally accompanied by instruments to sustain the voices, but the most artistic effect is produced by their perfect rendition unaccompanied. An interchange of melody, whereby the parts become in turn principal and subordinate, without any interweaving of them, does not constitute a quartet (see POLYPHONY). Quartets for stringed instruments are generally arranged for two violins, a viola or tenor violin, and a violoncello. Haydn was the originator of the modern instrumental quartet, and his contemporary emulators were Mozart, Beethoven, Gietry, Sammartini, Onslow, the two Rombergs, and Ries. Among later masters of the quartet form are Schubert and Brahms.

Quartier Latin, *kär-tê-â lâ-tân*. See PARIS.

Quartley, kwârt'lî, **Arthur**, American artist: b. Paris 24 May 1839; d. New York 24 May 1886. Coming to the United States in 1851, he studied in Baltimore and New York and was elected National Academician in 1886. His most important works are marines, and among them may be mentioned 'New York from North River'; 'Afternoon in August—Coast of Maine' (1778); 'Low Country on the North Shore of Long Island' (1881); and 'Off the Shoals.'

Quarto, the name applied to the size of a book, in which a sheet makes four leaves, frequently abbreviated to 4to. Also a book formed by folding a sheet twice, making four leaves, eight pages. The term, by modern usage, refers to a book of nearly square form.

Quartodecimans, kwâr-tô-dēs'î-manz, the name given to those Christians in the early centuries who celebrated the Easter festival on the same day as the Jews celebrated the Passover, namely the 14th day of the month Nisan. Most of the churches, both of the East and West, celebrated the Christian Passover always on the Sunday next succeeding the day observed by the Jews, never on 14th Nisan, even if that day was Sunday. The Council of Nice (325 A.D.) enjoined on all the faithful this rule; thereafter the Quartodecimans were held to be heretics.

Quartz, the name given native oxide of silicon, SiO₂. It is a widely distributed mineral, occurring not only as veins and segregated masses, but as a common constituent of igneous rocks. Detrital grains form sands, sandstones, and quartzites. Owing to differences in color and texture and its use as a semi-precious stone, the names given varieties of quartz are many. All these varieties, however, are included in two classes, the plainly crystalline or vitreous, and the obscurely crystalline called crypto-crystalline. All varieties have about the same hardness, 7, that is, can scratch window glass, and nearly the same specific gravity, 2.6. Pure quartz is fusible only at high temperatures.

Quartz crystallizes in the rhombohedral system, generally as six-sided prisms usually terminated at each end by six-sided pyramids. Among the crystalline varieties of quartz are rock crystal, amethyst, smoky quartz, rose quartz, milky quartz, the mineral being colorless when pure, but ranging through various shades of yellow, red, brown, blue, and green to black when impure. Colorless quartz, or rock crystal, is often cut into gem shapes and sold as Lake George diamonds, Brazil pebbles, etc. Perfectly clear crystals of larger size are highly prized in Japan, when cut and polished as spheres. Recently developed uses of rock crystal are in the manufacture of fibres for suspending the minute magnets and mirrors used as galvanometers and in the manufacture of spectrum tubes and test tubes, the quartz being fused by the oxyhydrogen blow-pipe. Quartz fibres are used for galvanometers because they show no torsion and the minors have no permanent set or deviation from the true position when at rest. Vessels made of fused quartz can be heated to a white heat and plunged into cold water without injury and on this account quartz tubes are used for studying the spectra gases at high temperatures.

QUARTZ PORPHYRY — QUATERNIONS

Of the colored varieties of crystalline quartz amethyst is clear purple or bluish-violet, and is popular as a gem; rose quartz, which always occurs massive, is rose red or pink; yellow quartz, or citrine, is often called topaz by jewelers, but may be distinguished from true topaz by its inferior hardness; smoky quartz, called also cairngorm stone, varies in color from smoky yellow to brownish black; milky quartz, white, nearly opaque and often with a greasy lustre, is of common occurrence in veins; sagenitic quartz has inclusions of needle-like crystals of rutile, actinolite, asbestos (cat's-eye) or black tourmaline; sapphire quartz indigo blue in color, is a rare variety. Many quartz crystals contain small cavities partly filled with liquids, generally water, also inclusions of carbonic acid, either liquid or gaseous. The cryptocrystalline varieties of quartz include chalcedony, and its varieties, carnelian, chrysoprase, prase, plasma, agate, onyx, and sardonyx; also flint, hornstone, touchstone, and jasper. Chalcedony has a wax-like lustre, is translucent or transparent, and its color varies from white through pale brown to dark brown or black, though it is occasionally blue; carnelian, or sand, is a red or brownish-red chalcedony; chrysoprase an apple-green variety; prase, a dull darker green; plasma, a leek green or emerald green; bloodstone, a dark green chalcedony with small red spots, like drops of blood; agate, a chalcedony with delicate parallel bands of color, or irregularly clouded color effects, the colors being white, red, brown, or even blue, while moss agate contains moss-like forms caused by oxide of manganese; in onyx the differently colored bands are straight and parallel; sardonyx is onyx containing bands of carnelian (sand); flint differs from chalcedony in being more opaque, having a slightly vitreous lustre, being generally gray or brown in color; it breaks with a sharp cutting edge; it was used by the early races of men for arrow heads, knives, etc.; hornstone resembles flint, but has a splintery fracture, and is often white; touchstone, known also as basanite or Lydian stone, a black hornstone or jasper, used for testing the purity of precious metals by rubbing them on it; jasper differs from the preceding varieties in being entirely opaque; it is often red, yellow, or brown.

Common milky quartz is used for a variety of purposes. In metallurgical operations it is used as a flux in smelting iron and copper ores; when finely crushed it is used by porcelain manufacturers for making glazes, quartz sand and ground pure quartz are used in immense quantities for making glass. Another use is as an abrasive, either as sandpaper or as sand or a fine powder. In these forms it is used for dressing stone, wood, and leather; while the powder, mixed with soap, forms a widely advertised cleansing compound.

Quartz Porphyry, an igneous rock characterized by containing crystals of quartz and feldspar with sometimes biotite and more rarely hornblende scattered through a ground mass that is glassy or contains fine crystals of quartz and feldspar. The name was formerly given to free Tertiary rhyolites and is still applied to rhyolites that have crystallized as dikes or laccolites rather than as surface flows, but these distinctions have little value. In general quartz porphyries differ from rhyolites simply in being denser. Quartz trachyte is a name given rhyo-

lite by European geologists. Quartz porphyries are of quite common occurrence in the Western States and are of peculiar importance at Leadville, Colo. See RHYOLITE.

Quartzite, a sedimentary rock of common occurrence in mountain ranges or when strata have been strongly folded. It is simply a metamorphosed sandstone, its hardness and rather crystalline character being due to the cement of crystalline quartz that surrounds the grains of the original sandstone. A sandstone containing clay becomes a quartzite containing mica, and thus quartzites grade into quartz-schists and mica-schists. In general, quartzites resist weathering and thus form ledges. They differ greatly in color. See also GLACIAL PERIOD.

Quasimo'do, in the Roman calendar, a term applied to the first Sunday after Easter, from the opening words of the introit for that day, "*quasi modo geniti infantes*," as infants lately born. Also the name of a well known character in Victor Hugo's novel 'Notre Dame de Paris.'

Quass, kwäs, or **Kvass**, a Russian beverage, made by pouring warm water on rye or barley meal. It is sour and fermented.

Quas'sia, a genus of shrubs and trees of the order *Simarubaceæ*. The best known species (*Q. amara*) is indigenous to tropical America, grows about 12 feet tall, bears large pinnate leaves with winged petioles, and racemes of bright red blossoms. The wood is used for cabinet making and for furniture, since it is avoided by insects. It is excessively bitter, and was formerly in repute as a medicine and for augmenting the bitterness of ale, porter, beer, and similar beverages. It is known also as bitterwood, by which name the wood of *Picræna excelsa* is likewise designated and used as a substitute for true quassia with which it vies in bitterness.

Quaternary, or **Post-Tertiary Period**, in geology, the fourth great division of the fossiliferous strata, which embraces the Pleistocene or Glacial and Post-Glacial (q.v.) and recent systems. See POST-PLIOCENE.

Quaternions. *Fundamental Principles*.—A quaternion, or "set of four," is a quadrimomial of the form

$$w + xi + yj + zk,$$

in which w, x, y, z are numbers, and i, j, k are four independent units, any three of which may be interpreted geometrically as a set of mutually perpendicular straight lines of unit length in three-dimensional space. The binary products xi, yj, zk are three mutually perpendicular line-segments of lengths x, y, z respectively; they are called *vectors*, while pure numbers, positive or negative, are called *scalars*.

The calculus of quaternions is an algebra in which the fundamental operations of addition, subtraction, multiplication, and division, and the consequent operations of involution, evolution, etc., are employed, and whose elements (operators and operands) are quaternions. It is a multiple algebra, because a quaternionic symbol, as q , contains implicitly several independent quantities, and it is essentially geometric, because its operations, addition, multiplication, etc., may be interpreted

QUATERNIONS

as geometric transformations. For example, in illustration of the last statement, if q, r be two quaternions and be taken to represent two line-segments meeting at a point, their sum is the diagonal of the parallelogram of which q and r are two adjacent sides. This is known as geometric addition; its law is that of the parallelogram of forces. Multiplication of a quaternion is equivalent to an orthogonal transformation in four variables plus an expansion or a contraction. The geometrical construction of a quaternion product, however, needs the hypothesis of a four-dimensional space for its proper presentation.*

Vectors in particular are so defined as to obey the law of geometric addition. If several vectors represent the successive parts of a broken line in space, their sum is the line-segment joining the free ends of the broken line. In this process of addition the line-segments representing vectors may be transferred to any positions in space, provided they remain parallel to their original directions, but the direction-sense must in every case be preserved.

In obedience to this interpretation a quaternion may always be written as the sum of a scalar and a vector; thus,

$$q = Sq + V'q,$$

wherein S and V are to be read 'scalar of' and 'vector of' respectively; for, by the law of geometric addition $xi + yj + zk$ is itself a vector, while w , being a pure number, is by definition a scalar.

In the quaternion algebra the laws of association and distribution in the four fundamental operations, and the law of commutativity in addition and subtraction, are assumed, or they may be derived from the geometrical definitions of the processes, but the commutative law in multiplication and division is rejected except for such quaternions as have vector parts that are numerical multiples of one another.

The laws of combination by multiplication are determined in the following manner: The mutually perpendicular vectors xi, yj, zk are numerical multiples of the three independent units, i, j, k , and the combinatory laws for these units are derived from the assumptions

$$i^2 = j^2 = k^2 = -1, \quad ijk = -1,$$

from which are obtained, through multiplication by i, j, k in succession, the remaining binary products

$$jk = -kj = i, \quad ki = -ik = j, \quad ij = -ji = k,$$

From these laws it follows that the product of two quaternions is itself a quaternion. Thus q and r being given quaternions,

$$q = w + xi + yj + zk, \\ r = w' + x'i + y'j + z'k,$$

their product has the form

$$qr = W + Xi + Yj + Zk,$$

wherein

$$W = ww' - xx' - yy' - zz', \\ X = wx' + w'x + yz' - y'z, \\ Y = wy' + w'y + zx' - z'x, \\ Z = wz' + w'z + xy' - x'y.$$

If the order of the factors in this product be changed from qr to rq , the scalar part $ww' - xx' - yy' - zz'$ is unaltered, but the terms $yz' - y'z, zx' - z'x, xy' - x'y$ change their algebraic signs and therefore the vectors of q and of rq are different. This result shows that in general quaternion multiplication does not obey the commutative law. In order that the above terms may not change sign (by a reversal of the order of the factors q, r) they must be separately zero, that is,

$$\frac{y}{y'} = \frac{z}{z'}, \quad \frac{z}{z'} = \frac{x}{x'}, \quad \frac{x}{x'} = \frac{y}{y'},$$

in other words, x', y', z' must be the same numerical multiples of x, y, z respectively. This makes $x'i + y'j + z'k$ a numerical multiple of $xi + yj + zk$, and it is the condition under which it is permissible to write $qr = rq$.

Division is interpreted by introducing the reciprocal, defined by the equation $qr = 1$, in which q and r are said to be reciprocal to one another, and, as in ordinary algebra, we write $r = q^{-1}$ and $q = r^{-1}$. This product obviously obeys the commutative law and also it has no vector part, so that

$$x' = nx, \quad y' = ny, \quad z' = nz, \quad [n = \text{a number}]$$

and

$$wnx = -w'x, \quad w' = -nw.$$

Hence the reciprocal of q must have the form

$$q^{-1} = \frac{1}{m} (w - xi - yj - zk),$$

where m is a number. By forming the product qq^{-1} , observing the laws $i^2 = j^2 = k^2 = -1, ij = -ji = k$, etc., it is easily shown that

$$m = w^2 + x^2 + y^2 + z^2.$$

This number is called the *norm* of q .

It is now evident that the quotient rq^{-1} is obtained by writing out the product

$$(w' + x'i + y'j + z'k) \cdot \frac{1}{m} (w - xi - yj - zk),$$

and that this quotient is a quaternion.

Hence, barring critical cases, such as division by zero, indeterminate forms, etc., the application of the four fundamental processes of algebra to quaternion symbols leads always to determinate quaternion results. The quaternionic algebra is therefore a closed system and satisfies the definitions of a group. (See THEORY OF GROUPS.)

The positive square root of the norm of q ($= +\sqrt{w^2 + x^2 + y^2 + z^2}$) is called its *tensor* and the quotient of q by tensor of q is called its *versor*, so that a quaternion is always the product of its tensor and versor. The symbolic form of this statement is

$$q = Tq \cdot Uq,$$

where T and U stand for tensor and versor respectively.

In the strictly symbolic notation the reciprocal of q has the form

$$q^{-1} = \frac{Sq - Vq}{T^2q},$$

and since $qq^{-1} = 1$ it follows that

$$S^2q - V^2q = T^2q.$$

* See 'Bulletin of the American Mathematical Society' (vol. 11, p. 437).

QUATERNIONS

The quaternions $Sq + Vq$ and $Sq - Vq$ are said to be *conjugates* of one another.

A vector has no scalar part, but it has a tensor factor and a versor (vector of unit length); and a scalar has no versor part, but it has a tensor, its positive numerical value, and a versor whose value is always ± 1 . The symbolic statements are

$$Vq = TVq \cdot UVq, \\ Sq = \pm TSq.$$

Therefore, also,

$$V^2q = -T^2Vq, \quad S^2q = T^2Sq.$$

The equation $S^2q - V^2q = T^2q$ may now be written

$$S^2q + T^2Vq = T^2q,$$

and hence, θ being an appropriate angle, it may be assumed that

$$Sq = Tq \cdot \cos \theta, \quad Vq = Tq \cdot UVq \cdot \sin \theta.$$

By the introduction of these expressions for scalar and vector the quaternion is presented in a new binomial form

$$q = Tq(\cos \theta + UVq \cdot \sin \theta),$$

one of great importance and utility.

The formula last written is a particular case of a more general geometric law. A recent interpretation makes quaternion symbols represent straight-line segments (their directions included) in four-dimensional space.* Interpreted in this way quaternions are called *directors*. It is shown that if two quaternion directors be perpendicular to one another their quotient is a vector. Let θ be the angle between p and q , let s be the director perpendicular dropped from the terminal extremity of q to p , and r the director from the origin (intersection of p, q) to the foot of this perpendicular. Then by geometric addition

$$q = r + s$$

and

$$q/p = r/p + s/p;$$

and s/p , being the quotient of a pair of mutually perpendicular directors, is a vector. Hence, if ρ be the ratio Us/Up , it is a unit vector and

$$q/p = \frac{Tq}{Tp}(\cos \theta + \rho \sin \theta).$$

When $p=1$ this equation reduces to the one previously written for the value of q . In this particular case θ becomes the angle formed by the quaternion director q with the axis of real quantities, or scalar axis. When p and q are both vectors the formula expresses the fact, on which Hamilton places early emphasis, that the ratio of two vectors is in general a quaternion, but that if the vectors meet at a right angle the ratio is another vector, if they be parallel it is a scalar. But the formula also shows that these statements are true of quaternions in general.

The two parts of the equation last written present the quaternion under its three most fundamental aspects:

1. It is the ratio of two directed, non-positated,† straight-line segments.

2. It is the sum of a number and a directed, non-positated vector.

3. It is the product of a tensor (tensor of q/p) and of a versor, the latter being expressed in terms of its angle θ , and its vector axis ρ .

The geometrical and kinematical interpretations of geometric addition and subtraction involve no special difficulties. They are fully explained in a variety of treatises in which this subject has its natural place, particularly in those parts of mathematical physics where the composition of velocities and of forces is explained. The first full exposition of the subject was given in the celebrated 'Barycentrische Calcul' of Möbius, published in 1827, and was therefore well known about sixteen years before the invention of the calculus of quaternions by Hamilton.

The non-commutative character of multiplication greatly enlarges its powers of expression and discrimination, but it also introduces troublesome transformation processes and calls for extended analysis. Fully expressed, the quaternion product has the double form $q()q_1$ and involves eight scalar quantities. A first step in its analysis resolves it, in either of two important ways, into simpler factors:

1. Since by the law of association

$$q()q_1 = 1[q()1]q_1 = q[1()q_1]1,$$

it consists of the two special commutative operators $q()1, 1()q_1$, applied in succession, or simultaneously, at pleasure.

2. It is always possible to determine four versor quaternions r, s, r_1, s_1 , that satisfy the following conditions:

$$Uq = rs = sr, \quad Uq_1 = r_1^{-1}s_1 = s_1r_1^{-1},$$

and

$$Sr = Sr_1, \quad Ss = Ss_1.*$$

The given product then assumes the form

$$mq()q_1 = mr[s()s_1]r_1^{-1} = ms[r()r_1^{-1}]s_1,$$

where m is a number. It consists of a tensor factor and two rotational transformations $r()r_1^{-1}, s()s_1$ which are commutative and may be applied simultaneously, or in succession.

The interpretation of the special products $q()1, 1()q_1, r()r_1^{-1}, s()s_1^{-1}$, as motions, "turns," and "rotations," generally in a space of four dimensions, has been successfully achieved.† An adequate account of them, however, would expand this notice beyond permissible limits. No accurate description of the motion represented by the general product $q()q_1$ has yet been given.

A simpler case than any of the preceding is the product $q()q^{-1}$. Its complete interpretation as a rotation in three-dimensional space was an early achievement by Hamilton himself. The motion consists of a rotation through twice the angle of q (q being given in the form $m[\cos \theta + \rho \sin \theta]$) about the vector of q as an axis; that is, any vector, placed at the origin, moves through the angle 2θ , on the

† Not placed in a definite position.

QUATERNIONS

surface of a cone having its vertex at the origin.*

Quaternion multiplications may be expressed in terms of matrices. This fact was first established by Peirce,† afterwards verified by Spottiswoode,‡ but more explicitly by Cayley.§ It has also been shown that every orthogonal transformation in four variables is expressible as a quaternion product.|| Such facts as these bring out clearly the multiple character of the quaternion algebra.

The further development of the theory of quaternions, which follows the exposition of fundamental principles outlined in the preceding paragraphs, includes the deduction of the formulæ of scalar and vector products and quotients, the interpretation and transformation of quaternion expressions in general, the differentiation of quaternions, the solution of equations, especially of equations of the first degree, and the analytical theory of quaternions.

But although the works of Hamilton and Tait contain a large mass of material concerning particular quaternion transformations, the general Analytical Theory of Quaternions has yet to be written. A brief outline sketch of a method is given by Cayley in the sixth chapter of Tait's *Treatise*.

Applications.—It is impossible, in the space permitted to this notice, to do more than name some of the subjects in which the method of quaternions finds its applications. The most important of these to which writers have thus far given attention are the following:

The theory of matrices; orthogonal transformation; geometry of the straight line, of the plane, of the sphere, of the cyclic cone, of surfaces of the second order, of curves and surfaces in general, and of planes in four-dimensional space; kinematics of a point, of a rigid system, and of deformable systems; axes and moments of inertia; statics of a rigid system; kinetics of a rigid system; precession and nutation; the problems of the pendulum; geometrical and physical optics; electrodynamics; the solenoid; applications of the

operator, $\nabla = i\frac{d}{dx} + j\frac{d}{dy} + k\frac{d}{dz}$, and of Laplace's operator ∇^2 , to physical analogies, to line, surface, and volume integrals, to the stress function; application of the ∇ integrals to magnetic problems; the hydrokinetic equations; applications of ∇ in connection with Taylor's theorem and the calculus of variations.

By far the greater portion of extant knowledge of quaternions, both of the theory and of its applications, is due directly to Hamilton and is published in the *'Elements,'* but the applications to physical problems were mainly contributed by Tait and are embodied in the twelfth chapter of his *'Treatise.'*

History.—The development of the quaternion calculus as an analysis of space relations was the work of Sir William Rowan Hamilton, Andrews Professor of Astronomy in the University of Dublin and Royal Astronomer of Ireland. The effort to create a new calculus of this type was a natural sequence of the many attempts that had been made to interpret geometrically the so-called imaginary and complex algebraic expressions of the forms $a\sqrt{-1}$ and $a+b\sqrt{-1}$. These attempts are recorded in the earlier works whose titles are given in the following bibliography.

Hamilton laid the foundations of the new subject during the years 1833-1843. In November of the latter year his first paper on *'Researches respecting Quaternions'* was presented to the Royal Irish Academy. His first full exposition of quaternion theory was published in 1853 in his *'Lectures on Quaternions,'* a book of over seven hundred pages.

Meanwhile, in 1844, Grassmann published his now celebrated work, *'Die Ausdehnungslehre,'* which occupies common ground with quaternion theory, but plans a much wider range of investigation than was contemplated by Hamilton in his system. The two systems have a common body of fundamental principles, but they have different points of view, different notations, and in part different purposes. Both form the foundations upon which all subsequent work of the kind must stand.

Hamilton's *'Elements of Quaternions,'* which still remains the storehouse of knowledge for its subject, was a posthumous work, published in 1866. A new edition has recently appeared in two volumes.

After the work of Hamilton and Grassmann had been finished the next most important forward step in the creation of new algebras was taken by Benjamin Peirce in his essay on *'Linear Associative Algebra,'* presented to the National Academy of Sciences at Washington in 1870, subsequently published in the *'American Journal of Mathematics'* (1881). In this work the author enumerates the types of linear associative algebras, and classifies them by a set of criteria which takes account of the number and the assumed laws of combination of their irreducible elements (extraordinaries, or vids). These laws are exhibited in the form of a series of multiplication tables.

Some of the more recent attempts to apply the quaternion analysis and the *Ausdehnungslehre* to physical problems have appeared under the title of *'Vector Analysis,'* sometimes with modified, sometimes with wholly changed notations. Of these the contributions of Willard Gibbs and of Heaviside should be mentioned as of special importance.

Bibliography.—The following bibliography, though not exhaustive, enumerates, in strict chronological order, the most important titles of books and monographs that have been published on the subject of quaternions and its closely allied branches. The later dates, where two or more are attached to a single title, are the dates of new editions, or of continuations of a series of papers: Wallis, *'Treatise of Algebra'* (1685); Abbé Bueé, *'Mémoire sur les Quantités imaginaire'* (read in June, 1805, *'Phil Trans.'* 1806); Argand, *'Essai sur une manière de représenter les*

QUATRAIN—QUATREFAGES DE BRÉAU

quantités imaginaires dans les constructions géométriques' (1806); Français, 'Papers on the Interpretation of Imaginaries in Gergonne's Annales' (1813); Gauss, 'Verwendung complexer Grössen für die Geometrie' (1819-1852) (Werke, Band VIII), and 'Theoria Residuorum Biquadraticorum' (1825, 1831) (Werke, Band II); Möbius, 'Der Barycentrische Calcul' (1827); Mourey, 'La vraie Théorie des Quantités Négatives et des Quantités prétendues imaginaires' (1828); Warren, 'Treatise on the Geometrical Representation of the Square Roots of Negative Quantities' (1828); Bellavitis, 'Calcolo delle Equipollenze' (1835); Hamilton, 'Papers in the Royal Irish Academy Transactions' (Vols. XVII, XXI), ('Philosophical Magazine,' etc., on 'Conjugate Functions,' 'Algebraic Couples,' and 'Quaternions' (1835-1843); H. Grassmann, 'Die Ausdehnungslehre' (1844 1862, 1878); De Morgan, 'Trigonometry and Double Algebra' (1849); O'Brien, 'Symbolic Forms Derived from the Conception of the Translation of a Directed Magnitude' (in 'Phil. Trans.,' 1851); Hamilton, 'Lectures on Quaternions' (1853); Allegret, 'Essai sur le Calcul des Quaternions' (1862); Hamilton, 'Elements of Quaternions' (1866); Tait, 'Treatise on Quaternions' (1867, 1873, 1890); Hankel, 'Vorlesungen über die complexen Zahlen und ihre Functionen' (1867); Benjamin Peirce, 'Linear Associative Algebra' (1870, 1881); Schlegel, 'System der Raumlehre' (1872); Clifford, 'Preliminary Sketch of Biquaternions,' in 'Proceedings of London Mathematical Society' (1873); Kelland and Tait, 'Introduction to Quaternions' (1873, 1882); Houel, 'Théorie des Quantités complexes' (1874); Laisant, 'Applications mécaniques du Calcul des Quaternions' (1877), and 'Introduction à la Méthode des Quaternions' (1881); Hardy, 'Elements of Quaternions' (1881); Gibbs, 'Elements of Vector Analysis' (1881-1884); Graefe, 'Vorlesungen über die Theorie der Quaternionen' (1883); Buchheim, 'A Memoir on Biquaternions,' in 'American Journal of Mathematics' (1885); Heaviside, 'Vector Analysis,' in 'Reprint of Electrical Papers' (1885-1892); Peano, 'Calcolo geometrico secondo l'Ausdehnungslehre di H. Grassmann' (1888); Hyde, 'The Directional Calculus' (1890); Macfarlane, 'Principles of the Algebra of Physics' (1891), and 'Papers on Space Analysis' (1891-1893); Kraft, 'Abriss des geometrischen Kalküls' (1893); Föppl, 'Vorlesungen über die Maxwell'sche Theorie der Electricität' (1894); Hime, 'Outlines of Quaternions' (1894); Hagen, 'Synopsis der höheren Mathematik' (vol. 2, 1895); Hathaway, 'A Primer of Quaternions' (1896); Macfarlane, 'Vector Analysis and Quaternions,' in 'Higher Mathematics' (1896); McAulay, 'Octonians' (1898); Stringham, 'On the Geometry of Planes in a Parabolic Space of Four Dimensions,' in 'Transactions of American Mathematical Society' (1901); Gibbs and Wilson, 'Vector Analysis' (1901); Hathaway, 'Quaternion Space,' in 'Transactions of American Mathematical Society' (1902); Henrici and Turner, 'Vectors and Rotors' (1903).

IRVING STRINGHAM,
Professor of Mathematics, Univ. of California.

Quat'rain, a poetical composition of four verses rhyming alternately, a usual form for epigrams, epitaphs, proverbs, etc.; stanzas of

four verses in a longer piece of poetry are also called quatrains, if each stanza expresses by itself a complete idea.

Quatre-Bras, *katr-brā* ("four branches"), Belgium, in the province of Brabant; at the intersection of the main roads from Brussels and Charleroi and from Namur to Nivelles; about 20 miles south-southeast of Brussels. It is famous for the battle fought here, 16 June 1815, between the English under Wellington and the French under Ney. It was Napoleon's plan at the opening of the campaign of 1815 to fight the armies of the allies singly, as he felt himself unable to cope with their combined forces. At the head of an army of 129,000 men, supported by 350 guns, he made a rapid march into Belgium, crossing the Sambre almost before the allies were aware of his movements. His army was divided into three corps: the right wing, 48,000 strong, being under Grouchy; the centre, of 28,000 men, under the emperor himself; and the left wing, of 48,000, under Ney. The Prussians and English under Blücher and Wellington lay between the French and Brussels. With the right wing and centre of his army Napoleon furiously attacked the Prussians, who, after a severe struggle, retired upon Wavre 16 June. On the same day Ney attacked Wellington at Quatre-Bras. The English, 32,000 strong, repulsed Ney, and maintained their position, though at a loss of over 5,000 men, including the Duke of Brunswick. The English general, hearing of the retrograde movement of the Prussians, fell back on the 17th on Waterloo, where the decisive battle was fought on the following day.

Quatre-Vingt-Treize, *katr-vān-trāz* ('Ninety-Three'), a work of historical fiction by Victor Hugo, published in 1874. The time is, as the title indicates, 1793. The scene is Vendée, during the civil war. In its style it displays much unevenness, but in its characters, vivid scenes, and tragic catastrophe ranks among the author's best.

Quatrefages de Bréau, *Jean Louis Armand de*, *zhōn loo-e ār-mān də katr-fazh də brā-ō*, French naturalist; b. Berthezène, Gard, France, 10 Feb. 1810; d. Paris, France, 12 Jan. 1892. He was graduated from the University of Strasbourg and in 1832 settled in Toulouse, where he practised medicine and shortly afterward founded the 'Journal de Médecine et de Chirurgie de Toulouse.' In 1838-40 he occupied the chair of zoology at the University of Toulouse and in the latter year removed to Paris, where he made a special study of invertebrates. In 1850 he was appointed professor of natural history at the Lycée Napoléon, Paris, and in 1855 professor of anthropology at the Musée d'Histoire Naturelle, which post he occupied until his death. He was elected to the Academy of Sciences in 1852 and was widely known by his anthropological investigations. He was the first expounder of the doctrine of phlebenterism, and was strongly opposed to Darwin's theories. He was the author of many important works on zoology and anthropology, among which are: 'Considérations sur les caractères zoologiques des rongeurs' (1840); 'De l'Organisation des Animaux sans vertèbres des côtes de la Manches' (1844); 'Recherches sur le Système nerveux, l'Embryogénie, les Organes des Sens, et la Circulation des Annélides' (1844-50); 'Physio-

logie Comparée, *Metamorphose de l'Homme et des Animaux* (1862); *Souvenirs d'un Naturaliste* (1854); *Histoire Naturelle des Annelés Marins et d'Eau Douce* (1865); *Les Polynésiens et leurs Migrations* (1866); *La Rochelle et ses Environs* (1866); *Rapport sur les Progrès de l'Anthropologie* (1867); *Ch. Darwin et ses Précurseurs français* (1870), an attack on Darwinianism; *La Race Prussienne* (1871); *L'Espèce Humaine* (1877); *Nouvelles Etudes sur la Distribution Géographique des Négritos* (1882); *Hommes Fossiles et Hommes Sauvages* (1884); *Introduction à l'Etude des Races Humaines* (1887-9); *Théories Transformistes* (1892); a series of papers entitled *Etudes sur les Types Inférieurs de l'Embranchement des Annelés*; and he also contributed a large number of articles to the *Revue des Deux Mondes* on the results of his scientific researches along the Atlantic and Mediterranean coasts and throughout Italy and Sicily.

Quatrefoil, kât'ér-foil, in architecture, an opening or a panel divided by cusps or foliations into four leaves, or more correctly the leaf-shaped figure formed by the cusps. It is an ornament which has been supposed to represent the four leaves of a cruciform flower, and is common in the tracery of Gothic windows. Bands of small quatrefoils are much used as ornaments in the perpendicular Gothic style, and sometimes in the decorated.

Quatremère, katr-mâr, **Etienne Marc**, French Orientalist: b. Paris, France, 12 July 1782; d. there 18 Sept. 1857. He was educated at the Collège de France, was employed at the Bibliothèque Impériale in 1807, and in 1809 accepted the chair of Greek in the University of Rouen. He was elected to the French Institute in 1815, became professor of Hebrew at the Collège de France in 1819, and in 1838 was made professor of Persian in the School for Living Oriental Languages. He made numerous valuable translations and was author of important geographical and historical works in addition to his work as an Orientalist. He published: *Recherches Critiques et Historiques sur la Langue et la Littérature de l'Égypte* (1808); *Mémoires géographiques et historiques sur l'Égypte* (1811); *Mémoire sur les Nabatéens* (1835); *Histoire des Mongols de la Perse* (1836); *Histoire des Sultans Mamelouks* (1837-45); etc.

Quatremère de Quincy, dô kân-sê, **Antoine Chrysostome**, French archæologist and politician: b. Paris, 28 Oct. 1755; d. there 8 Dec. 1849. He was prominent politically under the republic, consulate, empire, and restoration, in 1791 having been deputy to the legislative assembly for Paris. After the dissolution of the assembly, he was 13 months in prison, and after the proscriptions of 1793 he became one of the leaders of the insurrection of 5 Oct. 1795, for which he was condemned to death. He was later acquitted and in 1797 represented the Seine in the council of five hundred, but for his opposition to the revolutionists was banished, 5 Sept. 1797. The consuls recalled him in 1799, and in 1800 he was appointed secretary to the council of the department of the Seine; later was appointed to the class of history and ancient literature in the national institute; was made permanent secretary of the Academy

of Beaux-Arts in 1816, and was editor in that department of the *Journal des Savants*; elected professor of archæology at the Royal Library in 1818 and serving as deputy in 1820-1. He wrote: *Dictionnaire de l'Architecture* (1786-1825); *Histoire de la Vie et des Ouvrages de Rafael* (1824); *Canova et ses Ouvrages* (1834); *Le Jupiter Olympien, ou l'art de la sculpture antique* (1814); a treatise on ancient sculpture in ivory and gold; *Essais sur l'imitation dans les Beaux-Arts* (1823); *Monuments et Ouvrages d'art antique restitués* (2 vols., 1826-8); *Histoire de la vie et des Ouvrages des plus célèbres Architectes* (1836); etc.

Quattrocento, kwat-rô-chên'tô, in art, a term applied to the characteristic style of the artists of the 14th century; it was hard, rigid, and peculiar in color as well as in form and pose. It was the intermediate stage of that progressive period of art which, commencing with Fra Angelico, reached excellence with Leonardo da Vinci.

Quay, kwâ, **Matthew Stanley**, American politician: b. Dillsburg, York County, Pa., 30 Sept. 1833; d. Beaver, Pa., 28 May 1904. He was graduated from Jefferson College in 1850, studied law, was admitted to the bar in 1854, and elected prothonotary of Beaver County in 1856 and 1859. During the Civil War he was in active service as colonel of the 134th Pennsylvania regiment, being present at the battle of Fredericksburg; he was also assistant commissary general of Pennsylvania, State military agent at Washington, and military secretary to the governor. In 1865-7 he was a member of the Pennsylvania legislature; in 1872-8, and again in 1879-82, he was State secretary; recorder for the city of Philadelphia in 1878-9; and State treasurer in 1885. As early as 1869 he was secretary of the executive committee of the Republican State committee, and after that became the undisputed leader of his party in Pennsylvania. In national politics he was a member of the Republican national committee after 1885, and in 1888 was its chairman, conducting a successful Presidential campaign. In 1887 he was elected United States Senator, serving continuously till 1899; in that year a deadlock in the legislature prevented his re-election. This was in part owing to the fact that in 1898, on the failure of the People's Bank where State funds were deposited, he had been accused of being party to a conspiracy for the misappropriation of public funds; the trial occurred in April 1899, and resulted in his acquittal. He was then appointed Senator *ad interim* by the governor, and elected to the Senate in 1901 for the term expiring in 1905. In the Senate he was one of the strongest opponents of the Panama Canal. His power as a political organizer lay chiefly in his adroit methods of reconciling opposing factions and hostile interests. A striking example of this was his method of meeting the reform movement of 1902 by supporting as candidates for governor of the State and mayor of Philadelphia, men who were endorsed by the reformers and not prominent in the regular Republican organization, thus gaining the support of what might have been a dangerous opposition.

Quay, a landing-place along a line of coast or a river bank, or round a harbor. They

are usually constructed of stone, but sometimes of wood and iron. See *WHARF*.

Quayle, kwāl, **William Alfred**, American Methodist clergyman and author: b. Missouri 1860. He was graduated from Baker University, Baldwin, Kan., in 1885, was ordained to the Methodist ministry the next year and has since held prominent pastorates in Kansas City and Indianapolis. He was professor of Greek at Baker University 1885-90, and president of that institution 1890-2. He has lectured widely and has published: 'The Poet's Poet and Other Essays' (1897); 'A Hero and Some Other Folk' (1900); 'The Blessed Life' (1901); 'The Gentleman in Literature' (1902); etc.

Quebec, kwē-bèk (Fr. ké-bèk), is one of the provinces of Canada, the second in rank, in British North America. Its capital is the city of Quebec.

Boundaries and Extent.—It is bounded on the north by Labrador and Hudson Bay, on the east by Labrador and the Gulf of Saint Lawrence, on the south by the Bay of Chaleurs, New Brunswick, and the States of Maine, New Hampshire, Vermont, and New York, and on the southwest by the River Ottawa, Lake Temiskaming, and the province of Ontario. Its length is nearly 1,000 miles on a due east and west course, its breadth is 300 miles, and its area 351,873 square miles. The surface of the country is varied and very picturesque, embracing several ranges of mountains and lofty hills, diversified by numerous rivers, lakes and forests.

Mountains.—The Notre-Dame, or Green, Mountains, a continuation of the Appalachian Range, extend along nearly the whole of the south side of the Saint Lawrence. That chain runs more or less far from the river, and, after crossing the frontier and the State of Vermont, joins the Alleghanies. The Laurentian Mountains skirt the northern bank of the same river and the Ottawa, somewhere near, and somewhere at a distance of 10, 15, or 30 miles from the banks, but 130 miles west of Montreal cross the Ottawa and curve in the direction of Kingston, whence they run westward to the shores of Lakes Superior and Huron.

Rivers, Lakes, and Islands.—Quebec abounds in large rivers, bays, and lakes. The Saint Lawrence, navigable for ships of over 5,000 tons as far as Montreal, flows through almost the entire length of the province, receiving, a short distance above Montreal, the waters of the Ottawa, a river 600 miles in length. That last river is more abundant in water than the Nile and the Rhine, and has large tributaries, the rivers Gatineau and Lièvre (Hare), which are over 200 miles long, and three others extending over 100 miles to the north. The Saint-Maurice, which rises in Lake Oskelaneo and empties into the Saint Lawrence at Three Rivers, is over 400 miles in length and is remarkable by its enormous flow of water and its falls. The principal, named Shawenegan, Grand 'Mère, La Tuque, Les Piles, are wonderful water-powers. Large pulp mills and paper factories have been erected at Grand 'Mère and at Shawenegan, a few years ago, and are now the centre of towns numbering 5,000 or 6,000 inhabitants. The rivers Batiséan, Sainte Anne, Jacques Cartier, and Montmorency, the last named famous for its falls, also enter the Saint Lawrence from the

north. The Saguenay, rising in Lake Saint John and flowing into the Saint Lawrence at Tadousac, is one of the most remarkable bodies of water in the world, varying in depth from 100 to 1,000 feet. It is the great "exutoire" of the Lake Saint John, in which flow six long rivers; the principal one (the Peribonca) is 400 miles long and navigable for 30 miles. The Richelieu, draining Lake Champlain, discharges into the Saint Lawrence from the south, and so do the Saint Francis, Chaudière, Chateauguay, Yamaska, Etchemin, Bécancour, and from the north, Assumption, Matawan, and du Loup. The largest lakes in the province are: Lake Saint John, with an area of 360 square miles, the Mistassini, the Temiskaming, and the Temiscouata. At three places the Saint Lawrence enlarges and forms lakes, named Saint Francis, the Saint Louis, and the Saint Pierre. The principal islands in the river Saint Lawrence are the islands of Montreal, of Orleans, near Quebec, Anticosti, and the Magdalen Islands, situated in the Gulf of Saint Lawrence, 50 miles north of Prince Edward Island.

Forests.—The province of Quebec is wealthy in forest lands and the numberless rivers and their branches make the handling of lumber extremely easy. The territory on the north side of the Saint Lawrence River is covered with forests which are to all practical purposes valueless owing to the abundance of small growth. Along the River Manicouagan and the Gulf and River Saint Lawrence, the timber is not only of good quality but grows in great quantity, including even scattering pine of value. Extending westward from the Manicouagan to the eastern watershed of the Gatineau, pine of the best quality is found, and lumbering has for a number of years been successfully carried on. In the district from which the Saguenay and its branches draw their waters is a vast quantity of pine, spruce, larch, and other woods. In the district drained by the Saint Maurice and its tributaries pine and spruce are most abundant.

In the Lower Ottawa region, including the vacant and waste lands of the Crown on the northern tributaries of the Lower Ottawa, and embracing the valleys of the rivers Assumption, Dunord, Petite Nation, the Blanche, and du Lièvre, in all 11,256 square miles, are to be found poplar, white and red pine, spruce, tamarack, and birch. In the Upper Ottawa territory is a great pine-growing district, but, while it is more valuable than the forests of the southern part of the province, it has not been worked to the same extent as that part, where the marvelous growth of brown birch, cedar, walnut, maple, and pine has been a valuable source of income. Scattered throughout the province are to be found elm, beech, ash, and cherry trees. The area of the lands on which lumber of merchantable value is to be found (not including that covered by small growth) is 116,521 square miles, of which 31,468 are covered with red and white pine and 85,053 with other woods.

Mines.—The Laurentian formation, which extends through the central portion of the province, holds thick beds of limestone and iron ore, titanic and magnetic, phosphate, plumbagine, mica, and large deposits of graphite. Farther west the Laurentian formation is succeeded by the Potsdam sandstone. On this rests a dolomitic limestone, and the limestone of the Lower

QUEBEC

Silurian Age, known as the Chazy and Trenton groups, are affording the best building stone of the province. There are many other minerals in the province of Quebec; but a few of them only are worked up (exploitees), namely, asbestos, ochre, chrome, copper (near Sherbrooke), lead, silver, and gold in Beauce district. In 1901 there was a remarkable progress and increase manifest in the mining of asbestos throughout the eastern townships in Quebec, and copper also assumed a more important place in the mining industry. The report of the Bureau of Mines for 1900-1 shows that 193 prospecting permits and 12 mining licenses were issued, the greater portion of these going to operators of asbestos mines, who in that year employed 1,500 to 2,000 men, and whose product was valued at \$1,284,424. Pig iron to the extent of 14,449 tons was extracted by the blast furnaces at Radnor and Drummondville. The total value of the minerals extracted in the province was placed at \$1,727,731, including, with asbestos as its largest item, iron ore valued at \$30,978; copper ore at \$126,500; mica at \$39,600; ochre (calcined) at \$14,595; cement at \$28,000; and granite at \$146,000. The mining industry employed 2,792 workmen, whose wages amounted to \$865,110.

Climate.—The cold in Quebec in winter is generally steady; the thermometer often registers 20 degrees below zero, and the snow, falling to a great depth, lies on the ground from November until April. The extreme heat of summer, which is generally warm and pleasant, is indicated at 90°. But it is only exceptional that it runs up to that figure. Autumn, which lasts six or eight weeks, is the finest season of the year.

Agriculture.—Vegetation develops rapidly; there is a rich and loamy soil in much of the country. In the large valleys of the Saint Lawrence, of the Ottawa River, of the Matapedia, of the Richelieu, in the whole region of Lake Saint John, and in the eastern townships of the province, farming is the chief industry. The principal crops are wheat, barley, oats, rye, peas, buckwheat, potatoes, clover, hay, and corn. The lands lying in the vicinity of the State of Vermont are given to stock raising to a greater extent than to farming, and dairying has become an important branch of the trade of that district. As stated in the report of the minister of agriculture in Quebec, 1 Feb. 1902, the conditions have rapidly advanced and improved. The success of the plan of granting government premiums to cheese factories has been assured, up to that time over \$5,000 having been spent in pursuance of that policy, and now the products of such farms form a large part of the income of the farmer. In 1901 there were 1,207 cheese factories, 445 butter factories, and 340 factories of cheese and butter—the products of which having a total value of \$12,874,367. In the stock-raising districts horse and cattle breeding has assumed the most important position, while sheep and swine are also raised to a great extent; the value of the horses, cattle, sheep, and swine in the province in 1902 was \$2,413,416.

Fisheries.—The total yield and value of the fisheries of the province in the same year was \$2,174,459, salmon and cod making up more than half of this total. The number of vessels en-

gaged in the fisheries in 1901 was 786, having a tonnage of 25,605, and manned by 6,214 men.

Trade and Commerce.—The value of the imports entered for home consumption by the province in 1903 was \$93,183,449, and the value of the goods exported from the province in the same year was \$105,841,034. There are 183 banks (including branches) in the province, and a clearing-house at Montreal with annual transactions in 1903 of \$1,113,894,113. There are also 160 post-office savings banks in the province. There were, in 1903, 3,492 miles of steam railway and 178 miles of electric railway in operation in the province. The value of Quebec's mineral production in 1901 was \$3,761,639. The receipts of the province in 1903 were \$4,699,773, and its expenditures \$4,596,061, of which \$418,536 was used for charities and \$455,185 for public instruction. There are published in Quebec 15 daily newspapers, and 180 periodicals of other descriptions, or one for every 8,355 of population.

Education.—Educational matters in the province of Quebec are under the control of a superintendent of public instruction, assisted by a council consisting of 35 members, and divided into committees for the management of Roman Catholic and Protestant schools, respectively. Compulsory school age is from 5 to 16 years. The schools are maintained partly by local taxation and partly by government grants, and are individually controlled by local boards. There are in the province 5,379 elementary schools, 568 model schools, 1,781 academies, 3 normal schools, 19 classical colleges, 4 universities, 4 institutions for blind and deaf mutes, and 8 schools of arts and manufactures. Chief among the higher institutions of learning are Laval University at Quebec, and McGill University and the Presbyterian College at Montreal. There are also in the province 5 industrial and the same number of reformatory schools.

Government.—The system of government established in Canada under the Union Act of 1867 is a federal union having a general or central government controlling matters essential to the general development, the permanency, and the union of the whole Dominion, and a number of provincial organizations, each governed by a lieutenant-governor, nominated and removable by the government of the Dominion, and advised by a council responsible to the people's representatives, and with a legislature composed in Quebec of two houses—a council appointed by the Crown, and an elective assembly. The Parliament of Canada consists of a Senate and a House of Commons. The Senate, as at present constituted, has 81 members, 24 of whom are from Quebec. The House of Commons consists at present of 213 members, the basis of representation, fixed under the provisions of the Act of Confederation, being that the province of Quebec is always to have 65 representatives, and each of the other provinces such a number as will give the same proportion of representatives to its population as the number 65 bears to the population of Quebec as ascertained by a decennial census. In the province of Quebec the qualifications for the electoral franchise are ownership or occupancy of real property, position as teachers or clergymen after five months' domicile in electoral dis-

QUEBEC

trict: income or personal property of specified amount—real, or real and personal, valued at \$300, \$200, and \$100 (fishermen). Income, rentiers, \$100; others, \$300. Absentees in the United States may vote if they have returned with their families and have resided in an electoral district one month before election. Voting in elections is by ballot. No property qualification is demanded from a member of the Commons, nor is he limited to a residence in the district for which he is elected.

Municipal Institutions.—The municipal organization of the province comprises townships, counties, being rural districts of no definite area, parishes, villages with a population of over 40 families, towns, and cities erected by legislative authority. No definite figure of population is requested. The townships, parishes, towns, and villages are administered by a mayor and councilors; the cities by a mayor, councilors, and aldermen.

Judiciary.—The judiciary of the province consists of appeal (King's Bench), superior, circuit, and district courts. The superior court and King's Bench judges are appointed by the governor-general in council. Appeal can be had from superior courts to King's Bench, and from King's Bench to the supreme court of Canada, presided over by a chief justice and five associate judges. Final appeal, except in criminal cases, lies, by leave, to the judicial committee of the privy council of England. Police magistrates and justices of the peace, appointed by the provincial government, also have their place in the administration of justice.

Crown Lands.—The crown lands of the province not yet settled form an area of nearly 200,000,000 acres, of which about 6,625,000 acres have been surveyed, and are controlled by the government and administered by the minister of crown lands. They are sold at from 20 to 60 cents an acre, and the purchaser is required to take possession of the land within six months of the date of the sale, to occupy it during two years, and to fulfil various other obligations stipulated in the deed of sale.

Population.—The population of the province in 1903 was 1,682,682, of whom 477,687 dwelt in towns of more than 4,000 in 1901. The number of families in the same year was 307,304. Roman Catholics comprised the greater part of the population, in 1901 numbering 1,420,260, of whom 1,322,115 are French Canadians. The numerous churches, colleges, and convents of the province attest at every turn the wealth and power of the Church, and the tourist finds the whole land practically parceled out among its faithful, as far as concerns the nomenclature of the settlements and villages.

Twenty miles east of the city of Quebec, on the banks of the Saint Lawrence, is the church of Sainte Anne de Beaupré, more particularly known as La Bonne Sainte Anne, who for two centuries has won fame in Canada for miraculous cures. This historic place rests on a little plateau under the shelter of a lofty mountain of the Laurentides, and consists of a straggling street of wooden houses, with steep roofs and projecting eaves. Here one will see, on the fête of Sainte Anne and at other fixed times, a mass of people from every part of Canada, as well as from the United States. A handsome gray stone church attests the faith of the thou-

sands who in past years have offered their supplications at the shrine of La Bonne Sainte Anne. Piles of crutches are deposited in every available corner, as so many votive offerings from the countless cripples who have been cured or relieved. The relic through which all the cures are said to be effected consists of a part of the finger-bone of Sainte Anne, which was sent in 1668 by the Chapter of Carcassonne to Monseigneur de Laval.

The Country Life.—The situation of many of the villages of Quebec is exceedingly picturesque when they nestle in some nook by the side of river or bay, or overlook from some hill a noble panorama of land and water. The spire of the stone church rises generally from the midst of the houses, always making the most conspicuous object in the surrounding landscape. The houses are, for the most part, built of wood. The roofs are often curved, with projecting eaves, which afford a sort of verande, under which the family sit in summer evenings. Some of the more pretentious structures, especially the inns, have balconies running across the upper story. Many of the barns and outhouses have thatched roofs, which are never seen in any other part of Canada. The interiors are very plainly furnished, in many cases with chairs and tables of native manufacture. A high iron stove is the most important feature of every dwelling in a country where the cold of winter is so extreme. Whitewash is freely used inside and outside, and there is, on the whole, an air of cleanliness and comfort in the humblest cottage. No class of the population of Canada is more orderly or less disposed to crime. Early marriages have always been encouraged by the priests, and large families are the rule in the villages. The temperate habits of the people make them valuable employees in mills and manufactories of all kinds, and until a recent period there was a steady exodus from the province to the manufacturing towns of New England. A large proportion of the men employed in the lumbering industry of Canada is also drawn from the province of Quebec. In commercial and financial enterprises, however, the French Canadians cannot compete with their fellow citizens of British origin, who practically control the great commercial undertakings and banking institutions of Quebec, especially in Montreal. But they are remarkably progressing in that line. Nor, as a rule, could they compare formerly with the English population as agriculturists. But they have largely improved their methods of farming, and they have established in every parish butter and cheese factories. The French population also had less enterprise and less disposition to innovations. But they do adopt new machines and improved agricultural implements like the people of the other provinces of Canada.

Literature.—In times past there was no native literature, and little general culture, except in small select circles at Quebec and at Montreal; but during the past half-century, with the increase of population, the establishment of colleges and universities, the dissemination throughout of classical education, and the development of self-government, the French Canadians have created for themselves a literature which shows that they inherit much of the spirituality and brilliancy of their race. The histories and

QUEBEC

poems have attracted much attention in France, and some of their literary works have been awarded prizes by the French Academy. In history mention should be made of the names Garneau, Ferland, Sulte, Tassé, Turcotte, Dionne, Casgrain, Gosselin, Le Moine, Gagnon, Myrand, etc.; in poetry, Cremazie, Chauveau, Frechette, Poisson, Lemay, Chapman, and many others; in science, Hamel, Laflamme, De Foville, etc. In art some progress has been made, and young men go to the Paris schools from time to time. The only sculptor of original merit that Canada has yet produced is Hébert, a native of Quebec, whose statues of eminent Canadians stand in several places. Science has not made as much progress as belles-lettres and history, though Laval University has among its professors men who have done creditable work in mathematics, geology, chemistry, and physics. In romance, however, little has been done, except by Marquette, Lemay, and a few others.

History.—Jacques Cartier discovered and explored the Saint Lawrence in 1535, but it was not until 1608 that Samuel de Champlain founded the present city of Quebec, which, at the end of 12 years, had a population of only 60 persons. The Recollets were the first missionaries. The Jesuits came to the settlement in 1634, and thereafter played a leading part in its history. Montreal was founded in 1642 by Maisonneuve; but for many years as an agricultural or commercial settlement New France, as it was called, remained a failure, its only trade being the fur trade. A change came under Louis XIV., when a systematic effort began to make the colony the starting point of a French and Catholic empire which should embrace the whole of the continent. The result of this policy was a century-long contest between the two races, which began in 1689 with the second advent of Count de Frontenac as governor of New France, and ended in 1759 with the capture of Quebec by a British army under Wolfe. The capitulation of Montreal in 1760 completed the English conquest of Canada, which, with all its dependencies, was in 1763 formally ceded to the British crown.

The policy of the conquerors toward New France was, from the appointment of Gen. Murray, a liberal one, and in 1774 took definite form in what was known as the Quebec Act, by which the British Parliament assured the French Canadians the free exercise of their religion, the enjoyment of their civil rights, and the protection of their own civil laws and customs. The act also annexed larger territories to the province of Quebec, and provided for a governing council partly composed of Catholics, and for the administration of the criminal laws as in use in England. There was, however, constant strife between the conquering and the conquered race, the object of which was to amalgamate the two races, and to put an end to it Parliament in 1791 divided Canada into two provinces — Lower Canada, or Quebec, for the French, and Upper Canada (now Ontario) for the British, many of whom had fled thence from the United States at the close of the Revolutionary War. Each province was to have, besides the governor who represented the Crown, a legislative council nominated by the Crown, and an assembly elected by the people for four years. But the two races were not separated by the division of the

province, and in 1841, after a long and stormy agitation, a reunion of the provinces was effected under the name of the Province of Canada, and with it the establishment of responsible government. The legislature consisted of a council and assembly, each province being represented in the assembly by 42 members, 84 in all, elected by the people; and the council numbered 20 members, appointed by the Crown. This arrangement lasted until 1867, when it gave way to a union of the provinces of British North America. The way for confederation was cleared by a convention of representatives of all the provinces, held in Quebec, in October 1864, which unanimously adopted a set of resolutions embodying the conditions on which the provinces, through their delegates, agreed to a federal union. These resolutions were duly laid before the various legislatures and adopted in the shape of addresses to the Queen, whose sanction was necessary to embody the wishes of the provinces in an imperial statute; and in February 1867 the British North America Act was passed by Parliament. On 1 July of the same year the union of the provinces of Canada, Nova Scotia, and New Brunswick was proclaimed under the name of the Dominion of Canada, the names of Upper and Lower Canada being changed at the same time to Ontario and Quebec.

A. B. ROUTHIER,

Chief Justice Superior Court for the Province of Quebec.

Quebec, founded by Samuel Champlain in 1608, is the seat of the Provincial Government. It is situated on the northeastern end of a narrow promontory, which is bounded to the southward by the River Saint Lawrence, and to the northward by the valley of the St. Charles. The cliffs on the St. Lawrence side run up the river for many miles, and average between 200 and 300 feet in height. The earliest buildings were constructed along the narrow shore at the foot of Cape Diamond, and gradually extended to what is now the Lower Town. In the course of time Champlain transferred his residence to the summit of the rock, and soon other buildings arose which marked the beginnings of the Upper Town. In a few places in the Lower Town a part of the river bed has been reclaimed, particularly near the old palace of the Intendants; but with these exceptions the streets follow the original plan. Winding roads, cut out of the rock, and flights of steps, lead from the Lower to the Upper Town, the streets of which bear the names originally given to them. Quebec claims the distinction of being the one walled city of the north, and although the march of progress has introduced many innovations, it has been powerless to destroy the impress of the founder. At the time of the death of Champlain, in 1635, the entire population of Quebec was only 80 persons. But shortly after, as a result of the circulation of the "Relations" of the Jesuits in the mother country, an effort was made to colonize New France. The first fruits of this movement were the establishment of the Ursuline Convent and the Hotel Dieu, in 1639.

QUEBEC

These two institutions, which have ever since exercised a beneficent influence, were founded by the zeal of two noble women, Madame de la Peltrie, and Madame d'Aiguillon, whose names are consecrated in the pages of Canadian history. The Ursuline Convent has continued to be the centre of education for the girls of Quebec, both French and English. In this institution, the Old World and the New run side by side. The rule of the order is the same as in 1639. In the nave of the convent chapel repose the remains of the Marquis de Montcalm; and in the Chapel of the Saints, through all the startling changes of two centuries, the Votive Lamp, first trimmed by Marie Repentigny in the days of the French régime, is still kept steadfastly burning. The Seminary of Quebec, founded in 1668, is another institution in which the customs of the Old World are preserved. From the seminary sprang the famous Laval University, the chief seat of learning in the province for the French population.

From the earliest times Quebec has been fortified. In 1535, Jacques Cartier built a rude fort at the mouth of the river Lairet, and in 1608 the "Habitation" constructed near the site of the present Champlain Market, was mounted with cannon to protect the inhabitants against the incursions of the Indians. Twenty years after a fort was erected on the crest of the rock, which served as a residence for the invader Kertk until 1632. Frontenac put into execution the first scheme for enclosing the town with a wall, but like all the French works of defense, the profit of the contractor was of more importance than the solidity of the workmanship. In 1720, a new scheme was undertaken. Large sums of money were expended from year to year, but when Wolfe came before Quebec in 1759, the foot of rotten walls could be seen 500 yards off. After the battle of the Plains, temporary works were constructed in front of the old walls. In 1783 a temporary citadel was commenced beyond the line of fortification, and the remains of these works, still visible, are erroneously referred to in local guide books and maps, as of French origin. In 1823 the British Government undertook a comprehensive scheme of defense, the main parts of which are in excellent repair to-day. The picturesque old gates have been demolished, and in two instances, arches in keeping with the walls, have replaced them, and the Martello Towers, overlooking the Plains of Abraham, stand as originally built. The Fortress of Quebec comprises the citadel on Cape Diamond, where the governor general's quarters are situated, the town lines, and the forts on Levis Heights. The citadel is garrisoned by the Royal Canadian Artillery.

Quebec has nine parish churches belonging to the Catholics, four others in the charge of chaplains, and thirteen chapels attached to religious communities, open to the public. The Church of England is represented by the English Cathedral, and six churches, while the Methodists, the Presbyterians, and the Baptists, have each separate places of worship. The first parish church was erected in 1633 under the name of Notre Dame de la Recouvrance; but it was destroyed in 1640. In 1647 the French Cathedral was commenced under the name of Notre Dame de la Paix, in commem-

oration of the peace concluded with the Iroquois. It was opened in 1650. The pillars of the present church date from 1647, the Towers from 1684, and the remainder of the building from 1745. The paintings in the Cathedral, brought from France, are very valuable, and there are many costly vestments of an early date. Notre Dame des Victoires, in the Lower Town, was commenced in 1688 under the name of Notre Dame de la Victoire. After Phips besieged Quebec in 1690, a pilgrimage to the church was organized, and in 1711, on the destruction of Walker's fleet off Egg Island, the name of Notre Dame de la Victoire was changed to Notre Dame des Victoires. During the siege of Quebec in 1759, only the walls were left standing. Of the modern Catholic churches the Franciscan's is the most beautiful. It was built for the perpetual adoration of the Blessed Sacrament.

After the Treaty of Paris in 1763, English services were held by the Protestants in the Church of the Recollets. The drum was beaten at half past ten for the Mass of the Recollets, at the conclusion of which the fathers tolled the bell for the English service. The English Cathedral, situated on the site of the Recollet Church, was commenced in 1804. The paintings in the Archbishop's Palace, and in the Ursuline Convent and Laval University, are amongst the most valuable in Canada. In the Governor's Garden is a monument which always appeals to strangers. It is a plain granite column. On one side it bears the name of Wolfe, and on the other the name of Montcalm," and on the base this simple inscription:

Mortem virtus communem
Famam Historia
Monumentum Posteritas
Dedit.

It is the only instance on this continent of a common monument to the victor and the vanquished. Near the jail is the monument to Wolfe, with its inscription "Here Died Wolfe Victorious," and a little farther on, along the Ste. Foy Road, is the column to the memory of the French who fell in their endeavor to retake Quebec in 1760. The name of the English general, Murray, is also prominent on this column. These monuments of stone are more eloquent than words of the harmony existing between two races, mingling with each other, and still preserving their own laws, their language and their religion. In the Upper and Lower Town markets may be witnessed scenes typical of French Canadian habitant life, and even in the streets through which the electric cars run we may trace, at all times, the features of the French régime. The boys of the Seminary still wear the long blue coat piped with white, with green sashes, as they did 200 years ago. The nuns passing to and fro in their prescribed costumes; the priests in their cassocks, the habitants in their old-fashioned vehicles or rude sleighs, look out of place in the 20th century; and yet the people of Quebec would not welcome any change. The city, however, keeps pace with the times in other respects. The streets are well paved, well lighted, always clean. All the waste places possible are converted into small gardens, and there is an excellent civic administration. The hotel accom-

QUEBEC, CANADA

modation, especially since the construction of the Chateau Frontenac, is the best in Canada. The Parliament buildings and grounds, the city-hall, the court-house and other public buildings, are better than in the larger cities of Canada, and yet there is still so much which belongs to a by-gone age. According to the census of 1901, the population of Quebec is 68,840, a very large proportion of which is composed of French.

Most of the English reside in the Upper Town, although there is no marked division. The Grande Allée is the principal thoroughfare, and contains many fine dwellings. At one time the lumber trade flourished, and as large fortunes were amassed the wealthy merchants and traders built country seats along the Sillery Road; but they are now mostly deserted. Ship building was also a great industry for many years, as very large vessels were built there, but nothing now remains. The leather and shoe trade still give employment to thousands. The commercial and financial institutions are controlled to a large extent by the English. The Lower Town is principally devoted to business, and the suburbs of Saint Roch and Saint Sauveur to manufacture and the dwellings of the working classes. The small arms and the ammunition for the militia are manufactured in Quebec. The port of Quebec is always active in season, but Montreal has absorbed a great deal of the commerce. The bridge which is being built across the Saint Lawrence will bring the grain from all quarters to Quebec, and its future commercial life may assume large proportions. As the seat of government, it will always retain a prominent place, and in its immediate vicinity there are so many places of picturesque and historic interest: Wolfe's Cove; the place where the gallant Montgomery fell in 1775; the Heights of Levis; the Island of Orleans; the Village of Beauport, with Montcalm's headquarters; Indian Lorette; the Falls of Montmorency, with Wolfe's House; the Shrine of Ste. Anne, and the numerous places which may be reached by the C. P. R., the G. T. R., the Intercolonial Ry., the Great Northern, the Quebec and Lake Saint John, and the boats of the Richelieu and Ontario Navigation Co. But the perpetual charm of Quebec, apart from its magnificent situation, lies in the fact that it is the cradle of New France; that upon its lofty rock a drama was fought which decided the fate of a continent; that from its institutions, scarcely altered by the flight of three centuries, men went forth to rescue for civilization an untamed wilderness, and paved the way for the great Republic of the United States.

A. G. DOUGHTY,

Author of 'Quebec Under Two Flags.'

Quebec Act, the administrative measure passed by the British Parliament in 1774, for the purpose of adding the regions extending to the Ohio and Mississippi over which the French had exercised authority, to the province of Quebec, which had been limited by the Proclamation of 1763 to an area of about 100,000 square miles along the central Saint Lawrence. The Act established also the body of the French customary law as the permanent civil code of the region, the introduction of English civil law among the

French-speaking inhabitants having been found impracticable; it admitted also to a partial franchise the Roman Catholic population, guaranteeing them freedom of public worship, confirming them in the possession of their ancient churches and revenues, but withholding from them representative institutions, authority over this vast territory being vested in a council appointed by the executive power of Great Britain.

The Act, which had for its main motives the welfare of the French Canadians and the security and unhampered progress of the colonies and of colonial trade, was viewed with indifference by the Canadians, was unpopular in England, aroused the indignation of the older American colonies, and had considerable influence in directing the early course of the Revolution. To it the Declaration of Independence refers as follows:

"Abolishing the free system of English laws in a neighboring province, establishing therein an arbitrary government, and enlarging its boundaries so as to render it at once an example and fit instrument for introducing the same absolute rule in these colonies." For opposing views on the measure, consult: Coffin, 'The Quebec Act and the American Revolution' in *The Yale Review* (1895); and Bancroft, 'History of the United States,' Vol. IV., chap. v. (1884).

Quebec, Battle of. See COLONIAL WARS IN AMERICA.

Quebracho, kē-brā'chō, the name given to several trees of different genera, but with similar qualities, indigenous to South America, valuable alike for their wood and their bark. The red quebracho (*Loxopterygium lorentii*, family *Anacardiaceæ*) is very hard, but splits easily. The bark and wood are used in tanning. The white quebracho (*Aspidosperma quebracho*) is used for wood-engraving. Its bark contains an alkaloid (quebrachin) and is used therapeutically as a remedy for asthma, being employed as a decoction and a tincture. Its action is to lower the action of the heart without harmful result.

Quechua, kā'chwa. See QUICHUA.

Quedah, kā'da, or **Kedah**, Malay Peninsula, on the west coast of the peninsula, but belonging to Siam. It is bounded on the south by the British province of Wellesley and the province of Perak. Area, 3,600 square miles. Pop. est. (1903) 32,500.

Queen, the wife of a king, or the female sovereign of a kingdom. In Britain she is either merely a queen-consort, the king's wife, and his subject, not his equal, on an equal footing, save as provided by law, with the rest of his subjects; or she is a *queen-regent*, regnant, or sovereign, holding the crown in her own right, as did Elizabeth or Victoria. The *queen-dowager*, widow of the king, retains most of the privileges pertaining to a queen-consort. It is high treason to compass or imagine the death of a queen-consort, or to violate her person; and if the consort is consenting, she is equally guilty. Under the constitution of Prussia, Sweden, Belgium, and other European countries a woman cannot be queen-regent.

Queen Adelaide Archipelago, belonging to Chile, at the west entrance to the Strait of Magellan; separated from the mainland by Smyth Channel. The islands are mountainous and present rugged faces to the sea. The summits of some are snow-capped during the year;

QUEEN ANNE STYLE—QUEEN'S COLLEGES

but the vegetation at the base is varied and, for a short season luxuriant.

Queen Anne Style. See RENAISSANCE.

Queen Anne's Bounty, a fund established for the enlargement of the incomes of the holders of the poorer incumbencies in the Established Church of England, and to aid incumbents in rebuilding parsonages by granting advances of money. It was created by royal charter of Queen Anne, confirmed by act of the parliament, by which the first fruits (the whole of the first year's profits) of all spiritual preferments, and the tenth part of the annual profits of the same—both of which, prior to the reign of Henry VIII. had been paid into the papal treasury, but were then annexed to the crown—are set aside to form this perpetual fund. The fund is administered by a board of governors consisting of high ecclesiastical dignitaries, the speaker of the house of commons, privy councillors, chancellors of the universities, etc. It amounts to over \$25,000,000, and the annual grants to over \$75,000. To encourage private beneficence, the board of governors may give \$1,000 to incumbencies of not exceeding \$225 a year where an equal or greater sum is voluntarily contributed.

Queen Anne's Pocket-Melon. See MELONS.

Queen Anne's War. See COLONIAL WARS IN AMERICA.

Queen of the Antilles, a name given to the island of Cuba on account of its superior natural advantages.

Queen Charlotte Islands, a group off the coast of Canada, belonging to the Province of British Columbia; about 100 miles from the mainland and 135 miles northwest of Vancouver Island. Area, 5,100 square miles. The largest islands are Graham and Moresby, each about 160 miles long and 70 miles wide. The surface of Graham is rolling land; but the other islands are rugged and mountainous. Dense forests and a luxuriant growth of small plants cover the islands. Copper, anthracite coal, iron ore and gold-bearing quartz are found here; fishing is the chief occupation. The inhabitants are mostly Indians.

Queen Charlotte Sound, the body of water which separates Vancouver Island (q.v.), on the north, from the mainland of Canada. It is the first, on the north, of a series of inlets, or channels, which lie between Vancouver and other islands and the mainland.

Queen City, or Queen of the West, names applied to Cincinnati, Ohio, on account of its commercial importance, at a time when it was larger than Chicago and Saint Louis.

Queen City of the Golden Gate, a name given to San Francisco on account of the name of the strait north of the city, and also that the city was practically the gate or entrance to the gold fields of California.

Queen City of the Lakes, a name given to Buffalo, N. Y., on account of its commercial importance and its commanding position on the Great Lakes.

Queen Conch, a large West Indian gastropod (*Cassis cameo*). See CONCH.

Queen of the Eastern Archipelago, the island of Java; so called on account of its salubrious climate, picturesque scenery, and fer-

tile soil. It is the seat of the Netherlands power in the East. See JAVA.

Queen Esther. See MONTOUR, ESTHER.

Queen-of-the-Meadow, or Quaker-lady, a spiræa. See MEADOW-SWEET.

Queen of the Plains, a name applied to Denver, Colo., which rests on an eminence on the western border of the Great Plain, and seems to overlook the vast region of plain-land stretching off to the east.

Queen's Bench. See COURT.

Queen's College, Cambridge, England, founded in 1448 by Margaret of Anjou, queen of Henry VI., and again in 1465 by Elizabeth, queen of Edward IV., is administered by a president and 13 foundation fellows. A fixed proportion of the revenues of the college is paid to a scholarship fund. There are nine church livings in the gift of the college, and one in that of the president. There are in addition four exhibitions named after their founders, and the president distributes \$650 per annum in grants to deserving students of limited means. The college buildings are among the most interesting in the university, and include four courts of small size. In a tower in the pump-court are the rooms inhabited by Erasmus (1506). John Fisher, Thomas Fuller, and Bishop Pearson were members of the college.

Queen's College, London, England, established for women in 1848, was incorporated by royal charter in 1853. It provides for the higher education of women, first by a liberal school training, and subsequently by a six years' course of college education.

Queen's College, Oxford, England, was founded in 1340 by Robert Eglesfield, chaplain to Philippa, queen of Edward III., for a provost and 12 scholars. The college now consists of a provost, from 14 to 16 fellows, about 25 scholars, and two Bible-clerks. Six of the scholarships, annual value \$400, are called Eglesfield scholarships, and are awarded to natives of Cumberland and Westmoreland. There is also a scholarship called the Jodrell scholarship, of the annual value of \$450 and tenable for four years; and a considerable number of other exhibitions. The college presents to 23 church-livings. The college buildings are of the 17th century; the hall was designed by Sir Christopher Wren. Wyclif, Edward the Black Prince, Henry V., Addison, Bentham, Jeffrey, Mitford and Wycherley are numbered among its distinguished alumni.

Queen's Colleges, Ireland, three in number, are situated at Belfast, Cork, and Galway, and were chartered in 1849 in pursuance of an act of parliament passed in 1845, granting \$500,000 out of the consolidated fund for their establishment. The colleges were opened in 1850, being connected with Queen's University, then also instituted as a degree-conferring body. The corporate body of each college consists of the president and professors, and the general government and administration are vested in a council consisting of the president and six members, elected by the professors from among themselves. The number of students attending during the session of 1901 was 627.

Students of the Queen's Colleges in Ireland may obtain degrees in arts, medicine, and law

QUEEN'S METAL—QUEENSBERRY

from the Royal University of Ireland (q.v.) by observing the course of studies prescribed by that body, and passing the requisite examination. This university was founded in pursuance of the provisions of the University Education (Ireland) Act, 1879, and has now superseded the Queen's University in Ireland.

Queen's Metal. See BRITANNIA METAL.

Queen's Pigeon, a magnificent ground pigeon (*Goura Victoria*), inhabiting the islands of the Indian Ocean, named after Queen Victoria. See GOURA.

Queen's University, Kingston, Canada. The Royal Charter of Queen's University dates back to 1841. In 1838 steps were taken by the Synod of the Presbyterian Church to found a college at Kingston, Ontario, for the training of young men for the learned professions, including the work of the ministry. The beginnings, as usual with colleges, were small. The first classes with ten students were opened in March, 1842, with Dr. Liddell as principal. Funds were provided in part from grants from the Presbyterian Church of Scotland, and from the Canadian government, in part from the liberal subscriptions of friends of the young and growing university. Owing to the lack of good schools in the province, it was found necessary to establish a preparatory school in connection with the college. In spite of straightened circumstances and many obstacles progress was steady, and financial difficulties were overcome by the energy and courage of principal and friends.

Three times have appeals been successfully made to the public for the endowment fund: the first campaign under Principal Snodgrass took place at a time of great depression, and tided the college over a serious crisis. A second appeal was made by his successor, Principal Grant, in 1878-9, with brilliant success, and in 1881 a new building, an enlarged staff, and a great increase of students was the immediate result. Again in 1887 an effort was successfully made to raise the sum of \$250,000, which was called, in honor of the Queen's Jubilee, the Queen's Jubilee Fund. The twenty-five years of Dr. Grant's principalship were marked by extraordinary growth and development on every side of college life. Himself a tireless worker and a born leader of men, he succeeded in infusing his own enthusiasm into all around him.

At the time of the Federation of Colleges in Toronto Queen's was urged to join, but the proposal was decidedly negated by the friends of Queen's, and events have fully justified their decision.

The medical faculty of Queen's was established in 1854. It was reorganized in 1865 as the Royal College of Physicians and Surgeons in affiliation with the university. In 1891 the original status was resumed. The number of students last year enrolled was 216. Queen's led the way in Canada in co-education. As early as 1870 special classes in English and other subjects were formed for women, but the academic career leading to a degree was not thrown open to them till 1878-9. In 1880, co-education was extended to the medical course,

but in 1883 a separate Women's Medical College was opened and affiliated with Queen's. In 1894, similar facilities being offered in Toronto and other places, this college was closed. Meanwhile the extension of Queen's continued. 1891 saw the opening of the Carruthers Science Hall and of the School of Mines, the latter under government support, by whom the splendid building for physics and geology has lately been added. At the time of Principal Grant's death, in 1902, three new buildings were rapidly approaching completion. Since that time a magnificent Convocation Hall has been erected by the students and alumni to his memory. It is called Grant Hall. The group of college buildings at present consists of two arts buildings, with the Grant Hall, the engineering building, the physics and geology building, the Carruthers Science Hall, and the medical building.

The number of students registered in 1903, in all faculties, was about a thousand. Each session tells of increase. The government of the student body is largely carried on by the Alma Mater Society, which was formed in 1859-60. It has its own officers (taken from the students) and regular meetings, and has its official organ in the 'Queen's College Journal,' published entirely by students. The annual alumni conference brings many of the sons of Queen's back for a week's intercourse and renewal of old ties. The library, which is in the main arts building, contains about forty thousand volumes, including many valuable donations and collections. The curriculum of this university includes the following courses: The Arts Course, leading to the degrees of B.A. and M.A., D.Sc., and Ph.D., embraces classical literature, modern and oriental languages, English, history, mental and moral philosophy, political science, mathematics, physics, chemistry, mineralogy, geology, assaying, metallurgy, botany, and animal biology. The Law Course, leading to the degree of LL.B. The Theological Course, leading to the degree of B.D. The Medical Course, leading to the degree of M.D. and C.M. The Science Course, leading to the degree of B.Sc. and M.E.

GEO. Y. CHOWN,
Registrar of the University.

Queensberry, kwēnz'bēr-ī, John Sholto Douglas, 8th MARQUIS OF, English sporting character: b. England 20 July 1844; d. London 31 Jan. 1900. He served in the navy when a youth, and in the army from 1859 to 1864. His life was marked by much eccentricity. He was one of the founders of the Amateur Athletic Club in 1860, and was a recognized authority on boxing, and part author in 1867 of the prize-ring rules which bear his name. (See PUGILISM.) He sat in the House of Lords as a Scottish representative peer in 1872-80. In 1881 he published 'The Spirit of the Matterhorn,' a meditation in blank verse. He also came into prominence as a supporter of secularism, and as a defender of Charles Bradlaugh (q.v.), in 1882 creating a scene in a London theatre by rising in his seat and denouncing as "an abominable caricature" the imaginary free-thinker in Tennyson's 'Promise of May.' He was instrumental in effecting the imprisonment of Oscar Wilde

QUEENSBERRY — QUEENSLAND

(q.v.) in 1895, by defending the libel action brought against him, on the grounds that what he had published was "justifiable and for the public benefit."

Queensberry, William Douglas, 4TH DUKE OF. British sportsman: b. 1724; d. London, England, 23 Dec. 1810. He was devoted to horse-racing, and was familiarly known as "Old Q." He was vice-admiral of Scotland in 1767-76 and was then first lord of the police until the office was abolished in 1782. He succeeded to the dukedom in 1778 and was created a British peer in 1786. In 1789 he was removed from his office of gentleman of the bedchamber and held no further office. He was notorious for his excesses and was satirized by Robert Burns in 'The Laddies by the Banks o' Nith,' and in an 'Epistle to Mr. Graham of Fintrie.' Wordsworth addressed him in a sonnet as "Degenerate Douglas," and he was the original of the Earl of March in Thackeray's 'Virginians.'

Queensberry Plot, a presumed Scottish Jacobite conspiracy, so called owing to the connivance, in 1703, of the Proto-rebel James Douglas, second duke of Queensberry, with the intrigues of Simon Fraser, Lord Lovat (q.v.), to involve their common enemy, the Duke of Atholl, in a supposed conspiracy against Queen Anne. Atholl discovered the sham plot and revealed it to the queen. Queensberry, who had been a tool of Fraser, was compelled in consequence to resign his offices.

Queensland, Australia, a state of the Commonwealth, prior to 1901 a colony. It occupies the northeastern portion of the continent, north of New South Wales and South Australia, and east of the latter. The land boundaries are mostly artificial, the meridians of 138° and 141° east, and the parallels of 29° and 26° south; on the east it has the Pacific, on the north the Gulf of Carpentaria. The most northern part of it, forming York Peninsula, extends to Torres Strait, and a considerable portion is within the tropics. It has an area of about 668,497 square miles, and is divided into twelve large districts (besides smaller divisions), namely, Moreton, Darling Downs, Burnett, Port Curtis, Maranoa, Leichhardt, Kennedy, Mitchell, Warrego, Gregory, Burke, and Cook. Besides the capital of the state, Brisbane, the other important towns are Ipswich, Rockhampton, Toowoomba, Townsville, Mackay, Maryborough, Gympie, Bundaberg, Charters Towers, Normanton, Cooktown, and Somerset.

Topography.—A series of parallel ranges of mountains traverses the State from north to south near the coast, among the numerous local names being Cook Range, Razorback Range, Dawes Range, and Glasshouse Mountains. The Dividing and M'Pherson Ranges run from the head of the Dumaresq River in the south eastward to the coast. There is a long range in the interior running east and west, and forming a watershed between rivers flowing north and those flowing south. The peak of highest elevation is Wooroonooran in a spur of the Coast Range known as the Bellenden Ker Range. Its elevation is 5,400 feet. The coast is indented with numerous inlets, bays and harbors, some of the chief being: Moreton Bay, Hervey Bay, Port Curtis, Keppel Bay, Broad Sound, Repulse

Bay, Halifax Bay, Rockingham Bay, Princess Charlotte Bay. Among the numerous islands along the coast are: Stradbroke, Moreton, and Bribie, at Moreton Bay; Fraser or Great Sandy Island, Curtis, Whitsunday, Hinchinbrook, all off the east coast; Prince of Wales, Banks, Thursday, and others in Torres Strait; and the Wellesley Islands, in the Gulf of Carpentaria. Parallel to the east coast, and at no great distance, runs the Great Barrier Reef.

Hydrography.—There are four great river-systems: (1) rivers draining to the Pacific coast, the chief being the Burnett, the Fitzroy, the Burdekin, and the Brisbane, the last entering Moreton Bay, and having Brisbane, the capital, near its mouth; (2) those draining to the Darling, comprising the Macintyre, the Condamine or Balonne, and the Warrego; (3) those draining to the Gulf of Carpentaria, among them being the Flinders, the Leichhardt, the Albert, the Nicholson, the Gilbert, the Mitchell; (4) those flowing into the interior, the chief being the Victoria or Barcoo, which enters Lake Eyre in South Australia as Cooper's Creek, the Herbert, and the Diamantina or Mueller.

Geology and Mineral Resources.—The Cretaceous system is extensively developed in the west and northwest, covering an area of about 200,000 square miles. Tertiary strata occur along the coast of the Gulf of Carpentaria and elsewhere, and occupy a considerable area. The Desert or Eolian Sandstone, which renders extensive tracts barren and almost uninhabitable, is variously classed as Upper Cretaceous or Tertiary. Paleozoic formations also cover a large part of the country, especially along the eastern coast. About 14,000 square miles are Carboniferous, and some 40,000 of Devonian age, and the Cambrian and Silurian also occur. Mesozoic formations older than the Cretaceous are well developed in some places. Granitic rocks are very extensively developed in the east coast districts, and they have been estimated to occupy about 100,000 square miles. More than 30,000 square miles are covered by volcanic rocks. Gold was discovered about 1858, and there are now more than 25 gold-fields in the state, among them being Gympie (near Brisbane), Charters Towers (on the Burdekin), Cape River, Croydon, Cloncurry, and Jordan Creek. The annual production exceeds \$12,500,000. Other minerals of importance are copper, tin, and coal, but antimony, silver, lead, bismuth, manganese, plumbago, asbestos, and precious stones are also obtained. Bluestone, freestone, granite, and other rocks are quarried.

Climate.—The climate is healthful and the temperature comparatively equable. The mean temperature at Brisbane is 69°, the extreme range being from 35° to 106°. In the more northern parts the climate is tropical. The rainfall in the interior is scanty and variable; the mean at Brisbane is about 35 inches. In some parts it is now supplemented by means of artesian wells.

Forestry, Fauna, etc.—The state possesses various kinds of valuable timber, such as the red cedar, the Moreton Bay pine, the cypress pine, and several species of eucalyptus. Some of the grasses are valuable as fodder plants. There are several good indigenous fruits. The animals and plants are similar to those of the rest of

QUEENSTOWN—QUENSTEDT

Australia. Crocodiles are found in some of the northern rivers. Pearl-fishing is extensively carried on in the extreme north, and the bêche-de-mer, dugong, and other fisheries are also of some importance.

Agriculture.—The soil and climate are suited for the production of all the ordinary cereals, as well as maize, tobacco, coffee, sugar, cotton, and other plants. Maize is more generally cultivated than any other cereal crop. The next crop in point of importance is sugar. All kinds of semi-tropical and English fruits are abundantly grown. Sheep-farming is the chief industry, and cattle-breeding is also important.

Commerce, Manufactures, Communications.—The principal imports are apparel and haberdashery, cottons and woollens, flour, iron and steel, boots and shoes, tea, spirits, hardware, machinery, wine, etc.; and the principal exports, wool, gold, tin, sugar, preserved meat, cotton, wood, hides, and skins. The imports come mainly from the United Kingdom and the United States. The value of the total imports in 1901 was about \$31,880,000, of the exports \$46,245,000. A duty of 5 per cent is charged on imports of yarns, woven fabrics, paper, stationery, etc.; and duties at other and even higher rates on other articles.

The manufactures are comparatively unimportant; the chief industrial establishments are sugar-mills, steam saw-mills, soap-works, distilleries, breweries, carriage-works, butter-factories, boot and shoe factories, cordial-factories, etc. There are over 2,800 miles of state-owned railway open. The most important lines are the three which reach the coast at Brisbane, Rockhampton, and Halifax Bay. There are also over 10,240 miles of telegraph lines, and an extending system of telephonic communication; 684 vessels with an aggregate of 853,515 tons entered, and 675 vessels of 832,305 tons cleared the ports of the state in 1901.

Government, Education, and Religion.—The government is vested in a governor, who is the king's representative, an executive council, and a parliament of two houses, the legislative council and the legislative assembly. The council consists of 39 members appointed by the crown for life, and the assembly of 72 members elected by the people for three years, and representing 61 electoral districts. The revenue of the colony exceeds \$20,000,000, and the expenditure is usually less; the debt is about \$170,000,000. Education is free and secular in the state schools. A university is to be established for the state. There is no state church, each religious denomination being entirely self-supporting. Anglicans predominate, with Roman Catholics second.

History.—The first settlement of Queensland took place in 1825, when the territory was used as a place of transportation for convicts, who continued to be sent there till 1839. In 1842 the country was opened to free settlers. It was originally a part of New South Wales, until in December 1859, it was organized as a separate colony under its present name instead of the earlier one of Moreton Bay District. In 1901 it became one of the states of the Australian Commonwealth. Pop. (1891) 393,718; (1901) 503,266. See AUSTRALIA.

Consult: Russell, 'The Genesis of Queensland' (1888); Rutledge, 'Guide to Queensland' (1889); Weedon, 'Queensland Past and Present' (1897).

Queens'town, Ireland, a seaport town and important naval station, in the county and nine miles southwest of Cork, on Great Island, which is situated in Cork harbor, and rises abruptly to a considerable elevation. The streets rise above one another, and present a picturesque appearance. It has a splendid Roman Catholic cathedral. Queenstown is almost solely dependent on its military and naval establishments. It is an important port of call for mail steamers and was formerly known as COVE OF CORK. In honor of Queen Victoria's visit in 1849 the name was changed to Queenstown. Pop. (1891) 9,123; (1901) 7,909.

Queenstown, Ontario, Canada, village and picturesque summer resort of Niagara County, on the Niagara River, near the mouth of the gorge, seven miles below the falls, and opposite Lewiston, N. Y. Pop. 400. The Brock monument, 185 feet high, on the heights overlooking the village, commands a magnificent prospect, and commemorates the battle of 12 Oct. 1812, when Gen. Van Rensselaer commanding 6,000 United States troops near Lewiston, sent about 1,000 men across the river in the night to attack Queenstown preparatory to a further invasion of Canada. General Brock, the capturer of Detroit, commanded the British forces, but was killed early in the action. The rest of the American troops refused to cross the river, and the attacking party, overpowered by numbers, was compelled to surrender. The American loss in killed and wounded was 190, in prisoners 900; the British lost about 130 killed, wounded and prisoners.

Queiroz, kâ-ê-rôs', José Maria Eça de. See EÇA DE QUEIROZ.

Quelpart, kwêl'pärt, Quelpaert, or Tamra, an island off the southern coast of Korea, about 62 miles from the mainland. Tamra is the native name of the island. In form it is nearly oval; area, about 750 square miles. It is mountainous, the highest point, Mount Auckland, or Han-rasan, is 6,650 feet in height. This mountain is an extinct volcano; three well defined craters exist, in each of which is a lake of pure water. One of the traditions held sacred by many of the natives, is that from these lakes came the first three men of the world. The principal town is Chyei Chyu. The chief industries are fishing, agriculture, cattle-raising, and manufacturing fine split-bamboo hats. Pop. 81,000. Consult: Hamel, 'Narrative of Captivity in Korea,' in 'Korea Without and Within' by Griffis; Belcher, 'Narrative of H.M.S. Samarang,' containing an account of the survey and mapping of the island, by the officers of the British ship Samarang.

Quenstedt, kwên'stêt, Friedrich August, German mineralogist and geologist: b. Eisleben, Germany, 9 July 1809; d. Tübingen, Germany, 21 Dec. 1899. He was educated at Berlin and in 1837 became professor of geology and mineralogy at Tübingen where he remained until his death. He made valuable investigations in geology and mineralogy and in the latter science was first to apply the analytic method to the study of crystalline systems. He wrote: 'Methode der Kristallographie' (1840); 'Grundriss der bestimmenden und rechnenden Kristallographie' (1873); etc.

Quentel, kvěn'těl, **Heinrich**, German printer: b. Strasburg; d. 1501. He established a press near the cathedral at Cologne and though the earliest dated work from his press is 'Fratris Astexani Opus de Casibus Conscientiæ' (1479) yet the earliest Low German version of the Bible, usually stated 1470, is undoubtedly from his types and probably from his press. The business was conducted in his name for some time after his death.

Quentin Durward, kwěn'tin der'ward, a romance by Sir Walter Scott published in 1823. The scene of this tale is France during the reign of Louis XI.; the hero, Quentin Durward, is a Scottish archer, who, having a relative in the Scottish Guards of the French king, goes to France to seek his fortune. The book was written at the flood-tide of Scott's popularity at home; the ebb began with 'St. Ronan's Well,' published six months later.

Quérard, kâ-râr, **Joseph Marie**, French bibliographer: b. Rennes 25 Dec. 1791; d. Paris 3 Dec. 1865. From 1819 to 1824 he was attached to a well known Vienna book firm and while there prepared the first part of his 'La France Littéraire', in which he gives a complete bibliography of France for the 18th and the beginning of the 19th centuries, including not merely notices of French writers, but of foreign authors whose works had been reprinted or translated in France. The whole work appeared in ten volumes (1827-42). Among other works of his are: 'La Littérature Française Contemporaine,' of which Quérard himself prepared only the first two volumes (1839-44); 'Supercheries Littéraires Dévoilées' (1845-56).

Quercia, kwâr'châ, **Jacopo Della**, Italian sculptor: b. Quercia, near Siena, about 1371; d. 1438. He was the first Tuscan sculptor who combined observation of nature with study of the antique and thus reformed plastic art in Italy. His chief works are the sepulchral monument of Ilaria de Caretto in the cathedral at Lucca; a fountain adorned with the Madonna and emblematic figures of the virtues, Faith, Hope, Charity, Prudence, Justice, Temperance and Fortitude, at Siena; a marble font in the cathedral of the same city and the reliefs in the portal of the church of San Petronio at Bologna. Consult: Cornelius, 'Jacopo della Quercia' (1896).

Quer'citron, the internal part of the bark, used as a yellow dyestuff, of the black oak (*Quercus tinctoria* or *Q. velutina*), one of the finest of North American oaks (q.v.). The dye is due to a peculiar chemical principal, quercitrin, and is obtained by using alum or stannic chloride as a mordant. A finer yellow is said to be obtained when the decoction of the bark is previously boiled with dilute hydrochloric acid. In the United States it is used for tanning.

Quer'cus, the generic name for oak (q.v.).

Queres (K'eres, the aboriginal stock name), a group of Pueblo Indian tribes, numbering 3,582 individuals, in seven permanent villages on the Rio Grande and to the westward thereof, in New Mexico. They form the Queres, or Keresan, linguistic family, speaking a distinct stock language. The Indians claim to have had their origin at Shipapu, a mythic place in

the north, from which they gradually drifted southward and occupied, still in prehistoric times, the Rito de los Frijoles, west of the Rio Grande, where they excavated the cavate lodges in the soft volcanic tufa cliffs still to be seen. These were abandoned before the coming of Coronado, in 1540, who found them in seven pueblos (excluding Acoma and probably Sia) forming the province of "Quirix," along the Rio Grande. In 1630 they were reported by Fray Alonzo de Benavides to number 4,000, but this and other early estimates did not include Acoma. (See PUEBLO.) The present Queres pueblos are as follows;

Cochiti (native *Kot'yiti*).—On the west bank of the Rio Grande, 27 miles southwest of Santa Fé. In prehistoric times the natives of Cochiti and San Felipe formed one tribe, but on account of the hostility of the Tewas (see TANOAN INDIANS), they divided, the latter building a village near their present pueblo, the former settling in the Potrero Viejo, which they later abandoned, moving to near their present location, where they were found by Oñate in 1598. The Cochiti villagers were active participants in the Pueblo revolt of 1680, killing their missionary, but continuing to occupy their town. On learning of the approach of the Spaniards to reconquer their town a couple of years later, they fled, with the people of Santo Domingo and San Felipe, to the Potrero Viejo, where they remained almost uninterruptedly until 1692, when they were induced by Vargas to return to their homes. The Cochiti and Santo Domingo people again fled to the Potrero, however, where they were assaulted by Vargas in 1693 and severely defeated, 200 of their women being captured and their pueblo burned. Cochiti became the seat of the mission of San Buenaventura early in the 17th century. Of the 16 clans 4 are extinct. Pop. 300.

San Felipe (native name *Katishtya*).—On the west bank of the Rio Grande, 12 miles above Bernalillo. Formerly combined with the people of Cochiti, but independently occupying the vicinity of the present site at least since 1540. It was the seat of one of the earliest missions of New Mexico, its first church being erected prior to 1607. The inhabitants participated with those of Cochiti and Santo Domingo in the great revolt of 1680, but aided Vargas in dislodging the Cochiteños from the Potrero Viejo in 1693. They had no resident missionary at the time of the revolt, but aided in murdering the priests of Cochiti and Santo Domingo. After leaving the Potrero in 1692 the San Felipe people built a new pueblo on a mesa northwest of their present town, where a church (the walls of which are still standing) was erected in 1694. This was abandoned early in the 18th century and the present pueblo established, the fourth to bear the name Katishtya. Of the 30 San Felipe clans 9 are extinct. Pop. 550.

Santo Domingo (native name *Kiwa* or *Dyiwa*).—On the east bank of the Rio Grande, 18 miles above Bernalillo. In prehistoric times the inhabitants occupied successively the Potrero de la Cañada Quemada and two pueblos called Guipuy, in the latter of which, on the Rio Grande, they were found by Oñate in 1598. Like its predecessor, the second Guipuy, as well as Huashpatzena, the settlement which followed, was swept away by flood, and the present Santo

QUERETARO — QUERN

Domingo has had three similar but less severe disasters between its founding in 1692 and 1886, when a freshet destroyed its fine old church with carved doors bearing the Spanish coat of arms. At the time of the Pueblo rebellion of 1680, it was an important mission seat and the residence of the custodian of the province, who, with two other priests, were slain. The pueblo has 18 surviving clans and a population of 670.

Santa Ana (native name *Tamaya*).—On the northern bank of the Rio Jemez, a western tributary of the Rio Grande. Before the Spanish advent the inhabitants lived nearer the Rio Grande and in 1598 resided on a mesa between the present pueblo and San Felipe. They joined the San Felipe and Santo Domingo people in the great revolt, but in 1687 their village was carried by storm and burned, several of the natives perishing. The present town was built after 1692. It became a mission early in the 17th century, but had no resident missionary at the time of the rebellion. Santa Ana has 7 clans and a population of 238.

Sia (native *Tsia*).—On the north bank of Jemez River, 16 miles northwest of Bernalillo. It was formerly a pueblo of great importance, and in 1583 was said by Espejo to be the chief one of five towns forming the province of "Punames." It early became the seat of Nuestra Señora de la Asuncion. Its inhabitants made a most determined stand during the revolt of 1680, but in 1689 they were assaulted by the Spaniards, their pueblo wrecked, and the tribe decimated in the bloodiest engagement of the rebellion. Since this time the little tribe has been declining, its present population being about 125. Sia formerly had 37 clans, but of these only 16 survive.

Acoma (from *Akóme*, "People of the White Rock").—This pueblo and Laguna from the western division of the Queres stock. Acoma is picturesquely and strongly situated on a rock mesa, 357 feet high, about 60 miles west of the Rio Grande. It was first mentioned as "Acus" by Marcos de Niza in 1539 and visited by Coronado in 1540. Acoma has the distinction of being the oldest continuously occupied town in the United States. The natives treacherously killed several Spaniards of Oñate's force late in 1598, but in the following January the Spaniards led an expedition against the mesa, stormed and captured the town, killed about half the inhabitants, and burned some of the houses. Acoma became the seat of the mission of San Estevan in 1629; the natives murdered their missionary in the revolt of 1680, and remained in their fortified retreat until 1699, when they were induced to submit to the Spanish authorities. The present large adobe church, with its remarkable cemetery filled in with earth carried from the valley below, dates from the reconquest. In prehistoric times the Acomas lived on the summit of an even loftier mesa, known as Katzima, or the "Enchanted Mesa," three miles northeastward. According to tradition (verified by an examination of the summit and the surroundings of the mesa by F. W. Hodge in 1897), the only trail was washed away in a storm, leaving some of the inhabitants to perish; the village was henceforth abandoned. Population in 1680, 1,500; in 1760, 1,052; in 1902, 566. Of the 20 original clans 6 are now extinct.

Laguna (Span. "lagoon," from a lake formerly west of the pueblo; native name *Kawaik*).—The largest of the Queres towns, and the most recently established of all the southwestern pueblos, having been founded in 1697 by refugee Queres from other villages, particularly Acoma, as well as by Indians of other stocks. It is situated on the Santa Fé Pacific railroad, 17 miles northeast of Acoma. The town is being gradually abandoned, many of its inhabitants having moved permanently to their eight farming villages to the north and west. The Lagunas are very intelligent, honest and industrious, and are largely in demand as railroad laborers. The mission name of Laguna is San José, applied also to the rivulet on which the town is situated. The tribe has 20 clans. Population 1,143.

F. W. HODGE,
Smithsonian Institution, Washington, D. C.

Queretaro, *kā-rā'tā-rō*, Mexico, a state bounded on the north by San Luis Potosi, on the east by Hidalgo and Mexico, on the south by Mexico and Michoacán, and on the west by Guanajuato. Area, 3,556 square miles. See MEXICO—THE STATES OF.

Queretaro, Mexico, capital of the State of Queretaro, distant from the City of Mexico by the National Railway 167 miles and by the Central 153 miles, and from El Paso, Texas, by the Central 107½ miles and from Laredo, Texas, by the National 580 miles; elevation 5,004 feet above sea level. Here is the famous Hercules Cotton Mill, one of the oldest and most extensive in the Republic, employing almost 2,000 operatives, and here are also several other manufacturing industries, including woolen mills. Some miles distant are the famous opal mines, which have been worked for centuries, producing enormous quantities of the precious stones, but which are now becoming gradually exhausted. The water supply is obtained from the mountains through a great stone aqueduct five miles in length. The city has a complete system of electric lighting, a well equipped street railway and many substantial business structures. The Bank of Queretaro, with a capital of \$1,000,000, a branch of the National Bank and an agency of the Bank of San Luis Potosi supply the financial needs of the community. There are numerous churches, one of the oldest and most prominent of which is the Santa Rosa. The Civil College is the most notable educational institution. In this are taught law, engineering, chemistry, etc. There are two museums, one of which is devoted to history and the other to commerce; and a library connected with the Civil College contains 9,000 volumes. Other notable buildings are the Government Palace, built of basalt, the Iturbide Theatre and a bull-ring; there are also numerous parks. The city was founded by the Aztecs about 1440; was conquered by the Spaniards in 1531 and is noted in modern history as the scene of the capture, imprisonment and execution of Emperor Maximilian in 1867 by the Mexican government. Pop. (1906) 38,000.

Quern, a mill, especially a hand mill for grinding corn, used before the invention of water or windmills. It consisted of two circular stones, the lower of which was slightly dished,

and the upper one was pierced in the centre, and revolved on a wooden or metal pin inserted in the lower. The grain was dropped with one hand into the central opening, while with the other the upper stone was revolved by means of a stick inserted in a small opening or hole near the edge.

Quesada, kâ-sâ'thâ, **Gonzalo de**, Cuban diplomatist: b. Havana, Cuba, 15 Dec. 1868. He was graduated from the College of the City of New York in 1888 and afterward studied at Columbia. He was secretary of the Cuban revolutionary party and associated with José Martí in the endeavor to effect Cuban independence. He served as special commissioner of Cuba to the United States in 1900, was Cuban commissioner to the Paris Exposition, and in 1901 became a member of the Cuban Constitutional Convention. He has published 'Patriotism'; 'History of Free Cuba.'

Quesada, Gonzalo Ximenes de. See XIMENES DE QUESADA.

Quesaltenango, kâ - sâl - tâ - nân'gō. See QUEZALTENANGO.

Quesnay, kâ-nâ, **François**, French economist; b. Mérey, near Versailles, 4 June 1694; d. Versailles 16 Dec. 1774. He was at first a surgeon, and in 1737 was made perpetual secretary of the surgeons' academy; but in 1744 he received a physician's certificate and became a favorite physician at the court of Louis XV. His works on professional subjects are wholly antiquated and he is best known as the chief of those economists whom Dupont de Nemours called the "physiocrats." The principal tenets of this school were that there exists a natural order, with which human government should interfere as slightly as may be, and that all wealth is derived from the soil. Extravagant praise was heaped on Quesnay, who was called the "European Confucius," while his 'Tableau Economique' (1758) was styled by Laharpe "the Koran of economists." His economical works appeared in 1768. Consult Higgs, 'The Physiocrats' (1897).

Quesnay de Beaupaire, dè bō-rē-pâr, **Jules**, French jurist and author, known also by the pseudonym JEAN GLOUVET: b. Saumur 2 July 1838. He studied law, became for a time a journalist, later entered definitely upon a legal career, and in 1889 was made procurator-general of the Paris court of cassation. In that capacity he appeared for the government before the Senate, constituted as a high-court of justice with charges against Boulanger (q.v.) and the latter's accomplices, Dillon and Rochefort. In 1892 he was appointed president of the chamber of the court of cassation, from which post he was compelled in January 1899 to retire, owing to the fact that his aggressive attitude in the Dreyfus revision was interpreted by his colleagues as an evidence of bias. Among his works are: 'Le Forestier' (1880); 'Histoires du Vieux Temps' (1883); 'L'Etude Chandoux' (1885); 'France, 1418-29' (1895); and 'Le Panama et la République' (1899).

Quesnel, Pasquier, pās-kē-ā kâ-něl (PAS-CHASIUS), Roman Catholic theologian: b. Paris 14 July 1634; d. Amsterdam 2 Dec. 1719. In 1657 he entered the order of Oratorians, but subsequently through his publication of the

'Works of Leo the Great' (1675) with annotations, in which he maintained the independence of the Gallican Church, he incurred the displeasure of the Holy See, and as he refused in 1687 to subscribe to an anti-Jansenist declaration, he was obliged to take refuge in Brussels with Arnauld (q.v.) where he employed himself in completing his edition of the New Testament with moral reflections. The Jesuits, thereupon, obtained from Philip V. of Spain, a writ through which Quesnel was taken in custody as guilty of Jansenism (1703). With the aid of his brother, however, he escaped and fled to Amsterdam, where he lived to see 101 passages in his New Testament condemned by the Holy See in the bull 'Unigenitus.'

Quetelet, kêt-lâ, **Lambert Adolphe Jacques**, Belgian statistician and astronomer: b. Ghent 22 Feb. 1796; d. Brussels 17 Feb. 1874. In 1814, he became professor of mathematics at Ghent, in 1819 was appointed to the same chair in the Brussels Athenæum and was lecturer in the Museum of Science and Literature 1828-34. Quetelet superintended the erection of the Royal Observatory and was its first director from 1828 till his death. His writings on statistics and kindred subjects are very numerous, and among them may be named: 'Sur l'Homme et le Développement de ses Facultés, ou Essai de Physique Sociale' (1835); 'Sur la Théorie de Probabilités appliquée aux Sciences Morales et Politiques' (1846); 'Sur le Système Social et les Lois qui le régissent' (1848); 'Histoire des Sciences Mathématiques et Physiques chez les Belges' (1864); and 'L'Anthropométrie' (1871). He applied the mathematical methods of averages and probabilities to the study of man both as an individual and as a member of society.

Quetta, kwët'ta, British Baluchistan; city, on a railroad which belongs to the India railway system; and about 100 miles north of Khelat. It is a commercial and industrial centre for a large region; but it is of great strategic importance, on account of its position among high mountains and that it commands both Bolan and Khojok passes. It is strongly fortified, and has an arsenal and a garrison. It has become a flourishing place since 1876, when a British residency was established here. Pop. (1891) 18,802; (1901) 24,584.

Quetz'al. See TROGON.

Quetzalcoatl, a god of the Nahuas, primitive inhabitants of Mexico. The name Nahuas is applied to those tribes, apparently of the same origin, which successively ruled in Anahuac, or the Mexican Empire. All Nahuatl legends agree on the arrival in that region of certain bearded white strangers, garbed in black, who came to proclaim new doctrines to the Nahuas. These strangers have by some been without justification identified as Buddhist missionaries. The only definite information regarding them relates to their chief, who was called Quetzalcoatl, a name signifying, perhaps, "the serpent covered with feathers," though other meanings have been assigned. The earlier Spanish authors viewed Quetzalcoatl as St. Thomas, who had come, they thought, from India. The legendary material connected with him is extensive, varied, and confusing. He was worshipped as the incarnation of Tonacateatl, the serpent sun, and supreme deity in the Nahuatl mythology. Many temples

QUEUE ROUGE — QUICK-SAND

were built to him. Excavations everywhere unearth his image, in various guises in both stone and terra-cotta. His attributes were expressed in many bas-reliefs. American and European museums contain representations of him. A full account may be found in Bancroft (H. H.), 'Native Races of the Pacific States' (1875).

Queue Rouge, kē roozh, a West Indian name for a large spider much dreaded by the negros. See LATRODECTUS.

Quevedo y Villegas, kā-vā'thō ē vėl-yā'gās, **Don Francisco de**, Spanish author: b. Madrid 26 Sept. 1580; d. Villanueva de los Infantes 8 Sept. 1645. After study at the University of Alcalá, he was banished the country for having killed a nobleman in a duel, and went to Sicily, where he entered the service of the viceroy, the Duke of Osuna, by whom he was later made minister of finance in the administration of Naples. After his return to Spain he was arrested in 1639 on suspicion of having written some satiric verses against the king and ministry, and subjected to a four years' imprisonment, the rigors of which caused his death. He is best known for his prose satires, such as 'History of the Great Sharper, Paul of Segovia' (1627), and 'Visions' (1635). The latter were rendered into English by Sir Roger L'Estrange in 1708. There is a Spanish edition of his works by Guerra y Orbe (1852). Consult the study by Mérimée (1886).

Quezaltenango, kā-sāl-tā-nān'gō, or **Quezaltenango**, Guatemala, city, capital of a department of the same name, the second city of the Republic in size and in importance, 80 miles west of Guatemala city, at an altitude of 7,500 feet above sea-level. The town is well-built with wide and well-paved streets; among its handsome public buildings are the cathedral, city hall, and penitentiary. It has a considerable domestic trade, and manufactures of cotton and woolen textiles. A railway about 50 miles long connects Quezaltenango with Champerico on the Pacific coast. The city was founded in 1524 by Spaniards, on the site of a native city; there are numerous interesting antiquities in the neighborhood. Pop. (1898) 22,265.

Quiangán, kē-āng-ān', Philippines, a former Spanish commandancia, bounded on the north by Bontoc, now a part of the province of Lepanto; area 64 square miles; pop. 30,000. See LEPANTO.

Quianganes, kē-āng-ān'ās, a tribe of the Philippines, living in the commandancia of Quiangán, province of Lepanto, Luzon. They belong to the Ifugas linguistic stock, and are a headhunting people.

Quibdo, kēb'dō, Colombia, town in the department of Cauca, formerly the capital of the ancient province of Choco; on the Atrato River; about 30 miles from the Pacific and 200 miles northwest of Bogota. It was of considerable commercial importance when the gold mines of the vicinity were being worked; but the majority of the mines are (1904) abandoned owing to lack of use of modern methods of mining. The surface gold exists now only in small quantities. Pop. about 7,500.

Quiberon, kē-brōn, France, town, in the department of Morbihan; on the Bay of Qui-

beron, on a peninsula, about 22 miles southwest of Vannes. Nearby and on the peninsula are the noted megalithic monuments of Carnac (q.v.). Quiberon is now only a small fishing town; but it is of historical interest on account of the unsuccessful attempt of an English force to land here, in 1746, at the time of the Seven Years' war. On 20 Nov. 1759 Admiral Hawke attacked and overcame a French fleet under Admiral Conflans in Quiberon Bay, near the town. On 27 June 1795 a body of about 1,400 of French emigrant royalists landed here from an English fleet, and tried to arouse the people of La Vendée and Brittany against the Convention. They were repulsed by a force under General Hoche, some returned to their ships, and those who were taken prisoners were shot.

Quiché, kē-chā', or **Kiché**, an ancient nation of western Guatemala, the people of which were civilized and of the Mayan stock. Their language was a dialect allied to that spoken by the Cakchiquel. Their extant chronicles begin with the 8th century. In their sacred book, Popol Vuh, an account is given of the life of their great culture hero Xbalanque. This book gives many of the national traditions, written in the Quiché dialect. The first part of the book contains mythological accounts of their history, people, events, etc.; the second part is a detailed history of the origin of the tribe and some account of the Cackchiquel. The descendants of the Quiché now inhabit a large region in the central and western part of Guatemala. Consult: Ximenez, Spanish translation of Popol Vuh (Vienna, 1857); Abbé Brasseur de Bourbourg, French translation of Popol Vuh (Paris, 1861).

Quichua, kē-choo'ā, **Quechua**, or **Kechua**, the tribe who founded the Indian empire of Peru. The tradition as to the origin of this aboriginal empire is that it was founded by Manco Capac, the fourth son of the "creator god," Viracocha (q.v.). Much of the legendary and traditional history has been relegated to the domain of mythology by modern research, but the mythical tale was founded on some fact in nature or history. The descendants of this tribe, a large part of the population of the Peru of to-day, are still looked upon as being a superior people. In 1781 one of the tribe proclaimed himself as the reincarnation of the great Inca Tupac Amaru, gathered about him a number of zealous followers, led a revolt against the Spanish power, which was suppressed only after two years, and upon the capture of the leader, his family, and his leading followers. See PERU.

Quichuan (kē-choo'an) **Stock**, a South American Indian group composed of numerous tribes, chief of which are the Quichua (q.v.), inhabiting Peru, parts of Ecuador, Bolivia, etc. With the Aymaras the Quichuas composed the larger portion of the population of the empire of the Incas. The Quichua language, which was formerly the state language of the Incas, is still the chief speech of Peru, of a large portion of Bolivia, of the part of Ecuador bordering upon Peru, and of the northern section of the Argentine Republic. It is one of the most beautiful and at the same time comprehensive tongues of America.

Quick-firing Guns. See ORDNANCE.

Quick-sand, a tract of loose sand mixed with water which will not support heavy bodies.

In appearance quick-sands do not differ from the adjacent sands. They usually occur on flat shores underlain by stiff clay or other impervious materials and especially near the mouths of large rivers. They appear to be formed by the continued collection of water within the sand bank which is prevented from running off by the underlying impervious layer. The water which infiltrates the sand may be supplied, either by a river current, directed against a concave shore, or spreading over a sea-beach; by tides which at their ebb leave behind them imprisoned bodies of water; or by sea-currents running through narrow channels and forcing the water against the adjacent shore. The grains of quick-sand have rounded surfaces, as distinguished from angular or "sharp" sand. It is, moreover, of very light weight. The infiltrated water separates and lubricates the particles, rendering them unstable and unable to support a heavy weight, such as the body of a man. They have obtained a great reputation for treachery and danger, especially because they cannot be distinguished at sight. The subject has been drawn upon considerably in literature, notably in Hugo's 'Toilers of the Sea,' in Wilkie Collins' 'Moonstone' and in the 'Bride of Lammermoor,' with probably some exaggeration of the danger. The effect of quick-sands, however, is well illustrated by the sinking in 1875 of a locomotive and train at Pueblo, Colo., which sank beyond discovery though probed for to a depth of 50 feet. To make it possible to operate in quick-sands engineers are accustomed to congeal them by forcing into them brines and liquids at low temperatures.

Quicksilver. See MERCURY OR QUICKSILVER.

Quids, in American political history, a name applied to a faction of the Republican party led by John Randolph from 1805 to 1811. They were opposed to the nomination of Madison, Jefferson's choice for the succession. They declared war on the administration party in 1806, as governing Congress by backstairs influence. They opposed the restrictive system, and nominated Monroe in 1808. Their leading ground of divergence from the administration was that it had moved away from the ground occupied by the party when in opposition, and in the direction of centralization and federal encroachment.

Quietism, a tendency in religious devotion rather than any specific system of religion or mysticism. It consists in making Christian perfection a state of uninterrupted contemplation of divine things, the soul meanwhile remaining quiet and entirely passive under the divine influence, heedless of the customary precepts of practical religion, and without thought of rewards or punishments in another world, which are the master motives of vulgar piety. The term Quietism was first used to designate the mystical teaching of Miguel de Molinos (q.v.) who died (1696) in the prison of the Holy Office at Rome to which he had been condemned for teaching in sundry of his writings that the perfect Christian life consists in passive contemplation, unaffected by hopes or desires, and that the soul thus occupied neither gains by good works or acts of piety, nor suffers through the commission even of gross sins, for these affect only the lower nature of the devotee and cannot bring any stain upon the purity of a

contemplative soul. The amiable Fénelon (q.v.) was won over to hearty acceptance of some of the less objectionable features of Quietism by the influence of his disciple Madame Guyon (q.v.), several of whose mystical writings he approved and defended when they were condemned by the Gallican church authorities, among them Bossuet, bishop of Meaux, who declared them to be a "mass of extravagances, illusions, and puerilities." Fénelon's published apology for the doctrines of Madame Guyon having been censured at Rome as containing propositions rash, scandalous, etc., he promptly bowed to the judgment of the Holy See, publicly committing his own book to the flames.

Quietists. See RELIGIOUS SECTS; QUIETISM.

Quigley, James Edward, American Roman Catholic prelate: b. Oshawa, Ontario, Canada, 15 Oct. 1854. He was graduated from Saint Joseph's College, Buffalo, N. Y., in 1872. He then began his theological studies at the Vicentian Seminary, Niagara, N. Y., now Niagara University, and continued them at the University of Innsbruck, Austria, completing his entire course at the Propaganda, Rome, where, in 1879, he obtained the degree of doctor of theology, and was ordained priest 13 April of the same year. Returning to the United States, he was appointed pastor of the Church at Attica, Wyoming County, N. Y., and in 1884 was named rector of the Cathedral, Buffalo, N. Y. In 1896 he asked to be transferred to the rectorship of Saint Bridget's Church, Buffalo, made vacant by the death of Mgr. Gleason, but his residence in that parish was short, as, on 24 Feb. 1897, he was consecrated bishop of Buffalo to succeed Bishop Ryan, deceased. Bishop Quigley was chosen arbitrator in the great labor strike in Buffalo during 1904, and on 8 Jan. 1903 was promoted to the archiepiscopal see of Chicago. The archdiocese comprises (1905) a Catholic population of about 1,000,000; 619 priests; 316 churches; 168 parochial schools; 7 orphan asylums; 18 hospitals, and many other charitable and educational institutions.

Quill, the hollow stem of a feather (see PLUMAGE). Many utilities have been found for those of the larger size, but their use is declining. The principal use of quills is still for making pens, for which the feathers of the swan are most highly esteemed, but goose-quills are most commonly used. Crow-quills are said to be best for fine writing and drawing. In preparing quills for making into pens, they must first be cleaned inside and outside of fatty matter, which would prevent the ink from flowing freely. This is done by burying the quill-ends of the feathers for a few seconds in fine sand at a temperature of about 140° F. The quills are then polished and dried.

Quillaia (kwil-lä'yä) **Bark,** the bark of a South American tree (*Quillaja saponaria*), belonging to the division *Spiræa* of the order *Rosaceæ*. The tree has smooth, oval leaves, and white terminal flowers, solitary or in small clusters.

Quiller-Couch, kwil'ér kowch. **Arthur Thomas,** English author: b. Cornwall 21 Nov. 1863. He was educated at Oxford, where he was classical lecturer in 1886-7, and won some success with his first book, 'Dead Man's Rock' (1887). In 1887 he began a literary career in

London, where in 1889 he joined the staff of the 'Speaker,' the Liberal weekly newly established by Sir Wemyss Reid (q.v.). He retained until 1899 his connection with the 'Speaker,' a part of his contributions to which appear in the collections of short stories, 'Noughts and Crosses' (1891) and 'The Delectable Duchy' (1893). Among his further volumes are: 'Green Bays: Verses and Parodies' (1893); 'The Golden Pomp' (1895), an Elizabethan anthology; 'Ia' (1896); 'Adventures in Criticism' (1896); being selected reviews; 'The Ship of Stars' (1899); 'Old Fires and Profitable Ghosts' (1900); 'The Laird's Luck' (1901); 'The West-cotes' (1902); 'The White Wolf' (1902); 'The Adventures of Harry Revel' (1903); 'Hatty Wesley' (1903); and 'Shining Ferry' (1904). He also completed 'St. Ives,' left unfinished by Robert Louis Stevenson (q.v.). Much of his earlier work appeared over the pseudonym "Q." Much of his material he has derived from Cornwall, where he has made particular study of the Welsh poem.

Quil'iam, William Henry Abdullah, English Mohammedan writer: b. Liverpool 10 April 1856. He was educated at King William College, Isle of Man, and was admitted a solicitor in 1878. He visited Morocco in 1884 and became a Mohammedan the following year. He made subsequent visits to Morocco, Turkey and Persia, and in 1895 the Ameer of Afghanistan awarded him the title of Sheik-ul-Islam of the British Isles. He has been special commissioner for Canadian oaths since 1884 and has published: 'The Faith of Islam' (1887); 'Fanatics and Fanaticism' (1888); 'Religion of the Sword' (1889); 'Polly,' a novel (1891); 'The Ways of Sin,' a novel (1894); 'Moses, Christ and Mohammed' (1897); 'Studies in Islam' (1898); 'Manx Antiquities' (1898).

Quilp, kwilp, a malicious and hideous dwarf who figures prominently in Charles Dickens' novel, 'Old Curiosity Shop.' He torments and abuses his wife Betsey, and when about to be arrested for felony drowns himself.

Quil'ter, Harry, English artist and author: b. Lower Norwood, Surrey, 24 Jan. 1851. He was educated at Cambridge, studied at Bruges and in Italy, and in 1878 was called to the bar. In 1876-88 he was connected with various London newspapers, and in 1888-90 he conducted the 'Universal Review' which he founded. His first exhibition of paintings in oil was made at the Royal Institute in 1884, and in 1894 his collected works, 120 in number were exhibited at the Dudley Gallery. He is the originator of 'What's What,' first issued in 1902, and has published: 'Giotto' (1880); 'Is Marriage a Failure' (1889); 'Preferences in Art, Life, and Literature' (1892); etc.

Quimper, kăn pār', France, sometimes called QUIMPER-COËRENTIN, capital city of the department of Finistère, lying at the junction of the Steir and Odet, whence the name from Breton 'Kemper,' junction or confluence. It has the fine cathedral of St. Corentin, built in 1424. The old capital of Cornouailles, it figured in the religious wars. It has sardine-fisheries, breweries, paper-factories, tanneries, and a population of (1891) 17,406, and (1901) 19,441.

Quin, kwîn, **James**, English actor: b. Lon-

don 24 Feb. 1693; d. Bath, Somerset, 21 Jan. 1766. He was the son of an Irish barrister, and was educated in Dublin. In 1714 he went upon the Dublin stage, and a year after appeared at Drury Lane Theatre. In 1717 he went to the theatre in Lincoln's-Inn-Fields, where he remained 14 years, and acquired celebrity in characters of grave, dignified, and sententious tragedy, as in Cato, Zanga, and Coriolanus (in Thomson's tragedy of that name), and in those of strong, sarcastic, comic humor, as Falstaff and Volpone. In 1735 he returned to Drury Lane, on such terms as no actor had previously received; and he retained preeminence until the appearance of Garrick in 1741. In 1747 he was engaged at Covent Garden with Garrick; but the new actor obtained so great a share of attention that Quin retired from the regular stage in 1751. His last performance was Falstaff (1753), in which character he is supposed never to have been excelled. Garrick, once his rival and afterward his friend, wrote the epitaph for his monument in Bath Abbey.

Quinault, kē-nō, **Philippe**, French dramatist: b. Paris 3 June 1635; d. there 26 Nov. 1688. He studied law, but became a playwright, his first drama being produced when he was 18 and meeting with marked success. The continued success of his tragedies, comedies, and tragicomedies, of which he produced 16, made him a mark for the satire of Boileau, and he abandoned tragedy and engaged in writing librettos for the operas of Lulli. In this field he displayed great originality and though his success at the time was attributed to Lulli's music by Boileau and other critics, his verse is still read and admired while the music is forgotten. He was admitted to the French Academy in 1670 and his later years were spent in ease and comfort. Of his operatic pieces 'Armide' and 'Atys' are best known and of his dramas 'Astarte' (1663) and 'La Mère Coquette' (1665). Editions of his works were published in 1739, 1842, and 1880.

Quince, a shrub or small tree (*Cydonia vulgaris*) of the rose family: a native of central and eastern Asia, where it was cultivated more than 2,000 years ago and whence it has been introduced into all cool temperate countries of the civilized world. It is a close relative of the apple and pear, with which trees some botanists class it, but from which it is distinguished by having its flowers solitary upon the ends of twigs of the present season's growth. The popularity of the quince is limited because it is inedible in the fresh state, but it is highly prized for making preserves, jellies, etc., and as a flavoring for mixing with other fruits.

The plant is propagated mainly by stool layering, the rooted layers being grown in nursery rows usually two years after their removal from the parent bush. They are then planted from 10 to 15 or more feet apart, the distance depending upon the soil. On light soils the shrubs make rapid growth but are shorter lived and less productive than upon heavy. They should commence to bear when about three years old and reach full bearing when ten. Contrary to popular opinion the quince will do best when cultivated, but the stirring of the soil must not be deep because the feeding roots are rather close to the surface, especially if the soil be very moist. To obviate this danger, growers often

set the plants rather deeply and for the first few years work the soil away from them so as to induce deep rooting. They always use shallow rooting cover crops. It is another popular misconception that the plants do best in undrained soil. The best orchards of western New York, where the quince is an important crop, are upon well drained land.

The tree seldom grows more than 15 feet tall. It should be trained in bush form; that is, with several stems, though some growers prefer the tree form with only one stem. The latter seems more likely to be injured by borers. Beyond the removal of interfering, dead or unnecessary limbs the pruning consists of "heading-in" the twigs, a process which reduces the number of fruits. Being fairly hardy and a rather late bloomer the quince is a very regular annual bearer, but unless the tops be kept open and the quantity of fruits reduced the specimens will be inferior. Though the fruits ripen late and when gathered are generally very hard they should be handled very carefully and not be allowed to freeze. Except as indicated the management of a quince orchard is much the same as for pear orchard.

Among the insects which feed upon the quince are several borers, scale insects, caterpillars, plant-lice, etc., which are found on other fruit trees, especially apples and pears. These may be controlled in the same way. (See APPLE; PEAR; INSECTICIDE.) The quince curculio (*Conotrachelus crataegi*), a broad-shouldered snout-beetle of American nativity, lays its eggs in the fruit in early summer. It may be controlled like its relative the plum curculio. (See PLUM.) Several so called plant diseases common to the pear and apple are sometimes reported upon the quince. They have been combated in the same way as on the other fruits.

Consult: Bailey, 'Cyclopedia of American Horticulture' (New York, 1900-2); Meech, 'Quince Culture' (New York, 1896).

Quin'cke, Georg Hermann, German physicist: b. Frankfort-on-the-Oder 1834. He was educated at the universities of Berlin, Königsberg, and Heidelberg, and in 1859 was privat-docent at the University of Berlin. In 1872 he was appointed to a chair at the University of Würzburg, and in 1875 became professor of physics at Heidelberg. He has made important investigations of capillary phenomena, and valuable researches respecting electric influence upon different forms of matter.

Quin'cunx, an arrangement of five objects in a square, one at each corner and one in the middle. It is particularly employed in reference to the arrangement of trees. The term is frequently used in astronomy.

Quincy, kăn-sē, Antoine Chrysostome Quatremère de. See QUATREMÈRE DE QUINCY. ANTOINE CHRYSOSTOME.

Quincy, kwîn'zī, Edmund, American author, son of Josiah Quincy (1772-1864 q.v.): b. Boston, Mass., 1 Feb. 1808; d. Dedham, Mass., 17 May 1877. He was graduated from Harvard in 1827, was a prominent and able contributor to the anti-slavery press and wrote: 'Wensley' (1854); 'Life of Josiah Quincy' (1867); etc.

Quincy, Josiah, sometimes called JOSIAH QUINCY JR., American lawyer: b. Boston, Mass.,

23 Jan. 1744; d. at sea off Gloucester, Mass., 26 April 1775. He was graduated from Harvard in 1763, studied law in the office of Oxenbridge Thacher, and acquired a large practice. After the "Boston Massacre" (q.v.), he was selected with John Adams, by Captain Preston as counsel for the defense. He wrote many political pamphlets, and contributed much to contemporary journals. In 1774 he sailed for England, where he consulted with the friends of America, but died on the return voyage. An able orator, he was among the first to assume a bold revolutionary attitude. Though he incurred at the time some odium for his defense of Parker, his course was later strongly commended.

Quincy, Josiah, American statesman and educator: b. Boston 4 Feb. 1772; d. Quincy, Mass., 1 July 1864. He was graduated from Harvard in 1790, studied law and in 1793 was admitted to practice, and gave much study to political problems. By his oration in Old South 4 July 1798, he gained so extended a reputation that in 1800 he was made Federalist candidate for representative in Congress. Though defeated then through the ridicule of Republican journals, he was elected in the autumn of 1804 after having in the spring of that year been chosen to the State senate. He remained in Congress until 1812, when he declined re-election. He was a finished orator, spoke boldly on many difficult topics of debate, and was one of the most efficient members of his party, which during his whole term of service remained hopelessly in the minority. His statesman-like grasp of affairs is most clearly shown by the constant emphasis which he placed upon the increasing political danger with which the Union was menaced by the slave power. He feared civil war, and preferred a peaceable secession—a course not then seen, as it was later, to be impossible. In the State senate he urged Massachusetts to suggest to Congress an amendment of the Constitution, by which the clause permitting slave-States to reckon three fifths of the slave population in obtaining a basis for representation was to be stricken out. Of course, such a measure, had it succeeded, would have resulted in the dismemberment of the Union. Quincy opposed the annexation of the Louisiana territory, and in his speech of 4 Jan. 1811 took the advanced Federalist position that the Constitution did not confer on Congress power to admit any new States save such as might be formed from territory belonging to the United States in 1787. He declared that, if the bill passed, the Union was thereby dissolved, and that it would be the right of all States and the duty of some "to prepare definitely for a separation." This is believed to be the earliest enunciation in Congress of the doctrine of secession. Eventually Quincy acquiesced in the purchase, upon each of the original 13 States signifying its assent. He attacked the Embargo, and opposed the War of 1812, though, unlike many Federalists, he supported the administration, and on 25 Jan. 1812 made in the House a notable speech on the navy. Upon his retirement from Congress in 1813, he was at once elected to the State Senate, where he remained until 1820, then entering the House of Representatives, of which he was speaker until his resignation in 1822 to become judge of the Boston municipal court. In this capacity he was the first to hand down the ruling,

QUINCY

then much criticized but now accepted in the United States and England, that the publication of truth with good intent and for a justifiable end is not libel. From 1823 to 1828 he was second mayor of Boston; during his administration all the municipal departments were put in efficient working order. In 1829 he became president of Harvard, and this post he held until his retirement in 1845. In 1856 he was a supporter of Frémont for the Presidency. Besides several speeches, he published: 'History of Harvard University' (1840); 'History of the Boston Anthænum' (1851); 'The Municipal History of Boston' (1852); 'Memoir of John Quincy Adams' (1858), and other works. Lowell refers to him as "a figure of admirable example in a democracy as that of a model citizen." Consult: Quincy, 'Memoir' (1867); Lowell, 'A Great Public Character' in 'My Study Windows' (1867).

Quincy, Josiah, American lawyer, son of Josiah Quincy (1772-1864, q.v.): b. Boston, Mass., 17 Jan. 1802; d. Quincy, Mass., 2 Nov. 1882. He was graduated from Harvard in 1821, served as president of the Massachusetts senate in 1842, was mayor of Boston in 1845-9 and wrote 'Figures of the Past' (1882).

Quincy, Josiah, American politician, son of Josiah Phillips Quincy: b. Quincy, Mass., 1859. He was graduated from Harvard in 1880, and was admitted to the bar but never practised. He has been a leading member of the Democratic party, was chairman of that party's State Committee, and manager of the literary bureau of the National Committee in 1892. He served four years in the Massachusetts legislature, and in 1893 was appointed assistant secretary of state by President Cleveland, serving six months. In 1895 he was elected mayor of Boston and in 1897 re-elected, his progressive policy in regard to the extension of municipal functions attracting wide attention. He established the department of municipal statistics, a municipal printing-office and electrical construction department, greatly increased the number of public baths, and provided public lectures and concerts, and organized eight unpaid commissions to have charge of the city's charitable institutions, public baths and other improvements.

Quincy, Ill., the capital city of Adams County, is situated on the east bank of the Mississippi River, 264 miles south of Chicago and 160 miles north of St. Louis. It was, according to the census of 1900, the third city in the State of Illinois. It is built upon an elevated plateau 160 feet above the high-water mark of the Mississippi River. The water supply of Quincy is given from a reservoir with a capacity of 20,000,000 gallons at an elevation of 229 feet above the city, giving an average pressure of 40 pounds, the water before entering the reservoir being thoroughly filtered, making it absolutely pure. In consequence thereof the death rate has been materially decreased, making Quincy one of the healthiest cities in the world to live in. The pumping capacity is supplied by a triple expansion engine of 8,000,000 gallons daily and one compound engine of 4,000,000 gallons capacity daily, the water being filtered by 14 jewel gravity mechanical filters, therefore insuring the city over its distributing system of 45 miles of water

mains, an inexhaustible supply of water as the water is derived from an intake pipe from the channel of the Mississippi River. Quincy was settled and laid out by John Wood in the year of 1821 and to his memory there has been erected a statue in Washington Park, this being the principal part of the city. Quincy has a series of 16 nicely located parks situated in different parts of the city connected by a boulevard surrounding the city, and in all aggregating 152 acres. This in connection with the Illinois Soldiers' and Sailors' Home, which contains 140 acres, makes ample room for out-door recreation. The Illinois Soldiers' and Sailors' Home, situated upon these beautiful grounds of 140 acres, is complete in every detail and has a capacity for 2,000 veterans and the average attendance is about 1,700. Quincy's Federal building and court-house are buildings worthy of any city, so is the city-hall recently erected at a cost of \$140,000. The trade of the city is extensive and is distributed on several lines of railroad and the Mississippi River. Many of the streets are traversed by electric railways, the total extent of which is 27 miles, allowing people to go to all the principal business points and parks. The city is divided into seven wards. Of the public and charitable buildings the city contains two hospitals with the combined capacity of about 300 beds; 10 asylums and homes, and 33 churches, representing about all the denominations found in a community of the size of Quincy. Of public school houses there are 13, having been built at an aggregate cost of one half million dollars, with a corps of 114 teachers. The attendance of the public schools number 5,400 children. Besides these there are 12 parochial schools that have an attendance of 2,400 children with an attendance among the seven colleges located here that have an attendance estimated at about 1,500. The commercial interests of Quincy are represented by 1,500 firms with a capitalization of over \$15,000,000, embracing almost every kind of manufactory. Quincy is known particularly as a strong manufacturing city, there being 8 foundries with a capitalization of \$2,000,000, 7 machine shops with a capitalization of over \$1,000,000, 5 carriage manufactories with a capitalization of \$1,000,000, 5 flour mills with a capitalization of \$500,000; also the largest steam governor plant in the world, with a capitalization of \$500,000. There are also 6 breweries with a capitalization of \$1,000,000, also 4 incubator factories with a capitalization of \$1,000,000. There are also manufactories of furniture, plows, tobacco, organs, soap, files, and matches. Quincy is also well represented in the publishing line by 4 daily papers, besides numerous weeklies and monthlies, 19 in all. Pop. (1904 est.) 46,000.

H. HATCH, M.D.

Quincy, Mass., city in Norfolk County: on Quincy Bay, and on the New York, N. H. & H. railroad. The city includes within its corporate limits several villages; its area is about 16¼ square miles, nearly four square miles of which are in public parks. It is bounded on the north by Neponset River, and on the south by Fore River. It was settled in 1625 and was first known as Mount Wollaston. About four years later Thomas Morton (q.v.) obtained control of the settlement and established his "New Eng-

lish Canaan," "Merry Mount." His institution of the "May Pole" and other "Idolls," and his manner of living in general, offended the Puritans of Boston, and they thought him a dangerous man in the new country. He was arrested by Miles Standish and sent back to England. The place remained a part of Braintree until 1702 when it was incorporated as Quincy, after John Quincy. In 1888 it was chartered as a city.

The first railroad in New England was constructed here in 1826-7; it was two miles long, operated by horses, and used for carrying stone for building Bunker Hill Monument. There are many places of historic interest in and around Quincy, and some of the buildings of Revolutionary days are still in existence. Quincy came into great prominence the last quarter of the 19th century, on account of an educational movement under the leadership of Francis Wayland Parker (q.v.). Many prominent people have lived in Quincy; it was the birthplace of John Adams, John Quincy Adams, and John Hancock. The Adamses are buried under the old "Stone Temple."

Quincy is largely a residential suburb of Boston; but the quarrying interests are still of importance. It has also a large ship-building plant, machine and tools shops. It has a city hospital, the Woodward Institute, for girls; the Adams Academy, a high school, elementary public schools, and the Thomas Crane Public Library, which contains about 25,000 volumes. The Metropolitan District System supplies Quincy with water. The government is administered under a revised charter of 1900, which provides for a mayor and council, elected annually. The school board is chosen by popular vote. The mayor appoints the heads of all departments except that of the school board. The council elects the other administrative officials. Pop. (1890) 16,723; (1900) 23,899. Consult: Adams, 'Three Episodes of American History'; Hurd, 'History of Norfolk County'; Pattee, 'A History of Old Braintree and Quincy'; Wilson, 'Where American Independence Was Born'; Adams, 'The Centennial Milestone'; Report of U. S. Commissioner of Education, Vol. I. (1902), on the Quincy educational movement; Partridge, 'Quincy Methods.'

Quinet, kē-nā, Edgar, French litterateur: b. Bourg 17 Feb. 1803; d. Versailles 27 March 1875. He was educated at the schools of Charolles and Bourg and the Lycée of Lyons. His first publication was 'Tablettes du Juif Errant' (1823). A visit to Germany introduced him to Herder's 'Philosophy of the History of Humanity,' which interested him profoundly and gave direction to his life studies. He published a translation with an introductory essay in 1827. Living at Strasburg he met Victor Cousin and Jules Michelet, the latter of whom became his closest friend. In 1829 he was chosen by the French Academy to go to the Morea as philologist attached to a commission of *savants*, and on his return in 1830 published 'De la Grèce Moderne et de ses Rapports avec l'Antiquité.' His republican sympathies were stirred by the revolution in July and his feelings gained expression in political pamphlets. He wrote a remarkable prose poem 'Ahasuerus' (1833), and later two other epics, 'Napoleon' (1836), and 'Prométhée' (1838). His purpose in these

three was to represent humanity as general, individual, and religious—Ahasuerus, the race; Napoleon, the individual, and Prometheus, the martyr. In 1838 he published a reply to Strauss' 'Life of Jesus,' the next year was appointed professor of foreign literature at Lyons and in 1841 became professor of Southern Literature in the College of France. His Lyons lectures were published under the titles, 'Génie des Religions' (1842), and 'Le Christianisme et la Révolution Française.' His lectures delivered at the College of France attacking the Jesuits so aroused public feeling that the government closed his class-room in 1846. His republican opinions became so pronounced and his expression so outspoken that after the *coup d'état* of Louis Napoleon in 1851 he was banished from France. His exile, which lasted until after the fall of the Empire in 1870, was fruitful in such works as 'Marnix de Saint-Aldegonde' (1856); 'L'Histoire de Mes Idées' (1858); 'Merlin l'Enchanteur' (1860); and the 'Révolution Française' (1865). Re-established in Paris, he was elected to the Chamber of Deputies and voted consistently against all monarchical reaction and for the secularization of laws. His last work, 'L'Esprit Nouveau' (1874), contains an expression of his social, political and intellectual creed. His complete works were published in 30 volumes (1877-82). Consult his 'Lettres d'Exil' (1884); 'Edgar Quinet depuis l'Exil,' a biography by his widow (1888-9); Heath, 'Edgar Quinet: His Early Life and Writings' (1881).

Quingua, kēng'wā, Philippines, pueblo, province of Bulacá, Luzon; on the Quingua River, seven miles from its mouth; six miles north of the town of Bulacá. It is a road centre, and is a health resort for the surrounding provinces because of its pure water. Pop. 8,860.

Quinidine. See QUININE.

Quinine, kwín'ēn or kwí'nín, or **Quinina,** a drug ($C_{20}H_{21}N_3O_2$) most largely used in the cure of fevers. Technically known as a febrifuge (fever-cure), it is also a valuable tonic. Quinine is one of four important alkaloids obtained from the bark of the cinchona-tree (Peruvian bark; see BARK, PERUVIAN); the others being quinidine, cinchonidine, cinchonine (qq.v.). The curative power of these alkaloids is accurately shown by the report, dated April 1868, of a commission appointed by the British Indian government (Madras) after the suggestion of Clements R. Markham, C.B., F.R.S. Cases of fever numbering 2,472 were treated, and the result showed failures per 1,000 as follows: Quinidine, 6; quinine, 7; cinchonidine, 10; cinchonine, 23. Quinine alkaloid is seldom used, as it is very insoluble (59° F., 1,600 parts water). The salt known as quinine sulphate ($C_{20}H_{21}N_3O_2 \cdot H_2SO_4 + 7H_2O$) only is used.

The average dose of quinine sulphate for adults in the United States is 4 to 5 grains every 3 or 4 hours; in warmer and more fever-ridden countries, twice to three times this amount. The average consumption of quinine sulphate in the world at this time (1904) is 12,000,000 to 14,000,000 ounces a year, and the approximate average net cost of production is 18 cents per ounce, at which it will probably remain for a number of years, as there is very

little likelihood of any material change in the processes of growing cinchona-bark or making the quinine.

Production and Manufacture.—Cinchona-trees grow from seeds planted in hotbeds or nurseries, and are transplanted when they have reached a height of 3 or 4 inches. They are then left till they attain a height of about 3 feet, when *Chinchona ledgeriana*, the species yielding the largest amount of quinine, but growing very poorly in the ground, is grafted on to the stalk of *Chinchona succirubra*, which yields little quinine, but grows very thriftily. This combination gives the rich yield of the former with the healthy growth of the latter. After the graft has healed, these young trees are again transplanted to cleared places in the jungle. They are fertilized and attended carefully for six years, when they have reached their most profitable age. They are then sawed down at the ground, and sawed into sections, and native women beat the sappy bark from the wood with mallets. (All parts of the cinchona-tree contain traces of quinine, but the bark is the only part containing appreciable quantities of it.) The bark is dried in the sun for a day or two, then it is dried by a fire. Finally it is roughly ground, packed in bundles of 100 kilos (225 pounds) each, and sent to the market.

To manufacture quinine, the bark is ground to a No. 70 powder (screens of 70 meshes to the inch), and mixed with lime-water sufficient to moisten the powder thoroughly. It is then mixed with crude petroleum and boiled about five hours, the quinine in the bark dissolving in the oil. The powder is then allowed to settle, and the oil is drawn off and washed with dilute sulphuric acid, agitated violently with jets of air. The quinine now leaves the oil and goes to the acid-water, in which it is more soluble than in the oil. The oil and water now separate upon standing, and the acid-water is drawn off and neutralized with soda, when the quinine and other alkaloids are precipitated. The alkaloids other than quinine are separated from it, and the quinine is redissolved in dilute acid-water to saturation while hot. Upon cooling, crystals of quinine sulphate are thrown out, filtered, and dried for the market.

History.—The virtues of the bark of what was afterward known as the cinchona-tree were discovered by the Jesuits in Peru about the year 1600. Prior to that date the Indians evidently knew that it had remedial powers, but they did not use it to any extent. In 1638 the Countess of Chinchon, whose husband, Don Luis Geronimo Fernandez de Cabrera Bobadilla y Mendoza, was viceroy of Peru, was cured of an intermittent fever by the use of this bark administered by her physician, Don Juan de Vega, on request of Don Francisco Lopez de Cañizares, corregidor of Loxa. Upon her return to Spain in 1640 the countess carried a supply of the bark with her, and through her it became known to the world. It was very fitting that 100 years later Linnæus should name the genus of trees bearing this bark for the countess—*Cinchona* (Linnæus erred in spelling; it should have been *Chinchona*).

The actual discovery and isolation of quinine is to be ascribed to the French chemists Pelletier and Caventon in 1820, although Gomez, a Portuguese, succeeded in isolating the febrile

fuge principle, which was practically quinine, in 1816. Sulphate of quinine was first made in America in 1823, and the house of Powers and Weightman, which was founded five years before this date, was undoubtedly the first to manufacture it for sale. Until about 1850 the only source of supply was found in the trees growing wild on the sides of the Andes, and as quinine had become so valuable a remedy the world over, the native forests were almost exhausted so great had become the demand for cinchona-bark. The price had reached about \$20 per ounce. The Dutch, knowing that they had in Java climate, altitude, and temperature almost identical with those in Peru, determined to secure trees or seeds and try to cultivate it there. (Cinchona requires an altitude of 3,000 to 5,000 feet, tropical temperature, without much variation, from 100 to 200 inches of rain a year, and a volcanic soil.) The British government made the same attempt in India, but with poor results, because the same conditions of soil and rain do not prevail; and after about 50 years' endeavoring to raise cinchona in India and Ceylon, there only remain a few gardens owned by the government, the product of which is consumed in the army and among the natives, to whom it is sold through the post-office at cost.

The Dutch experiment, however, proved to be very successful and remunerative, although it involved almost insurmountable obstacles, loss of years of time, and lives of earnest working scientists. The trees now thrive tenfold more than even their Peruvian ancestors, for the congenial environment found in Java, together with the shrewd methods of cultivation discovered by the Dutch, the most faithful of whom has been Van Leersum, now government director of Cinchona Undertakings, who has not even left Java for a holiday in 25 years, gave yields of as high as 10 and 12 per cent; and the writer has taken bark from trees yielding as high as 16 per cent sulphate quinine, while an average of $1\frac{1}{2}$ to 2 per cent was a fair yield of the Peruvian trees.

There are now about 25,000 acres of cinchona plantations in Java, producing approximately 98 to 99 per cent of the cinchona-bark supply of the world, and in a few years there will be no supplies whatever from any other quarter.

F. L. SEELY.

Secy. Paris Medicine Co., St. Louis.

Quin'sext Council, or Council in Trullo, council of bishops held (692) in the hall named Trullus of the imperial palace at Constantinople. The design of this council was to supplement the purely doctrinal canons of the 5th general council (553) and of the 6th (660) with canons regulating discipline; for this reason it has been called in Latin *Concilium Quinisextum* (Latin, *quintus*, fifth, and *sextus*, sixth), and in Greek *Synodos Penthektē* (Greek, *pente*, five; *hektos*, sixth). It was attended by 211 bishops, all Oriental, and its decrees have ever been repudiated by the Western Church. Among the rules of discipline enacted by this council is one declaring married men eligible to the orders of subdeacon, deacon, and priest, but forbidding the marriage of one who is already in priest's orders.

Quin'nat Salmon, the foremost of the Pacific salmon in popular esteem and in commercial importance on account of its size, abund-

ance, and its habit of entering the rivers in the spring. It is known scientifically as *Oncorhynchus tshawytscha*, the specific name being a Latinization of that by which it was known to Russian fishermen about Bering Sea; Columbia Chinook, Sacramento and King Salmon are other names. It ascends the rivers early in spring, entering the Columbia as early as February or March, and goes to their headwaters to spawn, if not prevented,—those which succeed reaching the sources of this great watercourse about August or later. None returns alive from the spawning beds. "There is no other species of fish in the world," says Jordan, "equalling the Chinook salmon in commercial value. Of the five species of salmon on our West Coast it is approached in value only by the blueback. It reaches an enormous size; examples have been taken in Cook Inlet weighing 100 pounds, and individuals of 40 to 60 pounds weight are not infrequent. The average weight of those taken in the Columbia River has been stated to be 22 pounds, for those of the Sacramento River 16 pounds."

Quin'nipiac ("long water land"), an Indian tribe of the Algonquian linguistic stock, and probably forming a part of the Wappinger group, formerly residing on Quinnipiac River, New Haven County, Conn. Their principal village was on, or near, the present New Haven. In 1638 they numbered about 165; in 1735 they had increased to 250; in 1768 some of them moved to Farmington, where land was bought for them, in 1774 the original settlements were reduced to 38 natives.

Quinoa, *ke'nō-a*, an annual herb (*Chenopodium quinoa*) of the order *Chenopodiaceae*. It is a native of the Chilean and Peruvian Andes, and extends intermittently to Mexico. It grows about three feet tall, bears triangular leaves, very inconspicuous greenish flowers and large seeds. In general the plant resembles the common lamb's quarters or goosefoot (*C. album*), a well-known weed in American gardens. In South America and to some extent in Europe the plant is cultivated for its seeds, which are nutritious and are made into meal or fed to poultry. Its young tender foliage is also used like spinach, a related plant. Since it is a favorite food of certain insects it has not been profitably cultivated in California, where it was tried.

Quin'oline, **Chinolin**, **Leuconine**, C_8H_7N . Runge (1834) isolated an oily basic substance from coal tar to which he gave the name leuconine. Gerhardt (1842) obtained an oil by distilling quinine or cinchonine with caustic potash. He called it quinolein from its relation to quinine, but later the name was changed by Wöhler to quinoline. Hofmann (1843) showed that leuconine and quinoline were identical. It occurs also in bone-oil, and other plant alkaloids than those mentioned above give it with caustic potash. Usually made by the interaction of glycerine, sulphuric acid, aniline and nitro-benzene, and an oily liquid, colorless when pure, but becoming dark on exposure to the air, it possesses a penetrating, disagreeable odor, boiling point $239^\circ C.$, is slightly soluble in water and has a strong antiseptic action. It is a basic substance, forming soluble and easily crystallizable salts with acids. It is used to some extent as an antiseptic and in the preparation of a few dyes.

Quin'one, in chemistry, a class name which is applied to bodies that may be considered as derived from aromatic compounds by the replacement of two "ring" hydrogen atoms by two oxygen atoms. All the compounds of this class are colored and give colorless hydroquinones when reduced. Most of the quinones have the oxygen atoms in the "para" relations to each other. A very few "ortho" quinones are however known. The simplest and first known of this class is ordinary quinone or benzoquinone $C_6H_4O_2$; obtained by oxidation of quinic acid, but now usually prepared by oxidation of aniline with a mixture of dilute sulphuric acid and potassium bichromate. Its golden yellow prismatic crystals possess a peculiar pungent odor, and stain the skin yellow. Soluble in water or alcohol, they are volatile with steam and turn dark on exposure to the air. On reduction it gives hydroquinone $C_6H_4(OH)_2$, a soluble colorless crystalline body that is used extensively as a photographic developer. Quinone is a very active chemical substance, forming a large number of derivatives. Another very valuable member of this class is anthraquinone, $C_{14}H_8O_2$, a yellow crystalline body obtained by oxidation of anthracene. Related to it and obtained from it is the very valuable dye alizarine, the substance to which madder owes its value as a dye-stuff. See ALIZARINE.

Quinquagesima, *kwīn-kwā-jes'ī-ma*, **Sexagesima**, **Septuagesima**, the 1st, 2d and 3d Sundays before Lent. The words mean, respectively 50th, 60th and 70th, and in the Roman calendar the names of the three Sundays are *Dominica Quinquagesimæ*, *D. Sexagesimæ*, and *D. Septuagesimæ*, respectively. The use of the words is ancient, dating at least from the 7th century, but their meaning is obscure. Alcuin (9th century) suggested the numeration of 70 days from *Dominica Septuagesimæ* down to *Pascha Clausum*, the octave of Easter; but that leaves the other two names unexplained. Another explanation offered by Alcuin was that these two names are formed on the analogy of *Quadragesima* (Lent), being one and two weeks before the first Sunday in Lent: a false analogy, which assumes 7 to be equal to 10; but false as it is, it led to calling the second week of Lent *Tricesima* (thirtieth) and the third *Vicesima* (twentieth).

Quinquarticular Controversy. See ARMINIANISM.

Quinsy, an acute inflammation of the tonsils; acute parenchymatous tonsillitis. It is attended by fever, pain, headache, difficulty in swallowing (dysphagia), and frequently by suppuration. One attack seems to predispose to another. It is not uncommon for individuals to have attacks year after year at about the same time of the year. Disturbances of the digestive organs—diarrhœa, constipation, loss of appetite, nausea, vomiting, etc., are predisposing causes. Sudden changes of weather, exposure to damp and cold, especially after coming out of a heated room, are exciting causes.

Quinsy sets in with an uncomfortable feeling in the throat, and fever sometimes high, preceded at times by chilliness. The patient is restless and irritable, the tongue becomes covered with a thick yellowish coating, the breath is unpleasant, saliva drools from the mouth, there is

QUINT — QUINTILIUS

difficulty in opening the mouth, swallowing is attended with great effort and pain, and sometimes food returns through the nose. Pain may be severe most of the time, shooting toward the ear upon the affected side. Swelling externally behind the ears and involving the glands of the neck may be marked. A thick tone of the voice, thirst, headache, snoring, and dryness of the throat are common symptoms. Sometimes breathing is impeded, especially if both tonsils are involved. On examination of the throat one or both tonsils are seen to be bright red and sometimes covered with patches of a yellow secretion. The soft palate is red, greatly swollen, and oedematous, as is also the uvula, which not infrequently adheres to the tonsil. Quinsy may terminate either in resolution or suppuration. If resolution is to take place, in about four or five days the inflammation begins to subside, and the patient in from ten days to a fortnight may resume his ordinary employments. If suppuration is to occur, the tonsillar swelling becomes greater, and if both tonsils are inflamed they may meet, causing great discomfort. When pain and discomfort become almost unbearable, an inflamed tonsil generally breaks, and great relief and speedy convalescence follow.

Occasionally, if the disease is taken at the outset, it can be aborted by a purgative, or an emetic, and the use of one or two drops of tincture of aconite every hour. If it continues in spite of early treatment, it will probably run its course, though much can be done to palliate. Keep the patient quiet (sometimes in bed), and give hot or cold liquid foods, whichever he can swallow best. Washing out the throat with hot water every hour may be comforting, as also may inhalations of the steam of hot water, cooled by passing through a towel or a long tube. Saline laxatives are useful; so are hot compresses about the neck. Ice and cool drinks have an efficacious value. Local applications and the use of medicines and stimulants should be left to the judgment of the physician. Abscesses should be opened (not left to mature) and astringent gargles afterward used.

Quint, kwint, **Alonzo Hall**, American Congregational clergyman: b. Barnstead, N. H., 22 March 1828; d. Boston, Mass., 4 Nov. 1896. He was graduated from Dartmouth College in 1846, from Andover Theological Seminary in 1852, and was ordained to the ministry in 1853. He became chaplain of the 2d Massachusetts volunteers in 1861 and served with them until 1864. After the war he was pastor of several Congregational churches successively, edited the 'Congregational Quarterly' in 1859-76, and was author of: 'Army Notes' (1864); 'Records of the 2d Massachusetts Regiment, 1861-5'; etc.

Quin'tain, an apparatus used in a military sport or exercise by men on horseback, formerly practised in England to try the agility of the country youth. The quintain was an upright post with a cross-bar on the top of it, turning round on a pivot. To one end of the bar was suspended a bag of sand, the other end was broad and flat. The horseman had to ride tilt at the flat end with his lance, and endeavor to strike it and pass on before the bag of sand could whirl round and strike him on the back.

Quin'tal, a weight of 100 or 112 pounds,

according to the scale used. See WEIGHTS AND MEASURES.

Quintana, Manuel José, mă'noo-ěł hō-să' kēn-tă'nă, Spanish poet: b. Madrid, Spain, 11 April 1772; d. there 11 March 1857. He was educated in the university at Salamanca, studied law, engaged in practice at Madrid, where he occupied several government offices, and soon turned his attention to literature. He was author of almost all the manifestos and proclamations issued in the war of independence and his patriotic poems soon won for him great popularity. He edited the journal 'Variedades de Ciencias, Literatura, y Artes,' founded the 'Semanario Patriótico,' and urged upon the people the necessity for resisting Napoleon. After the restoration he was imprisoned in 1814-20, and then was released by the revolution. He lived in retirement from 1823 until 1833 when he was appointed preceptor to the infant queen, Isabella. In 1835 he was elected senator and was afterward highly esteemed at court. He was one of the leading poets of his time, attaining a European reputation. As a historian he is well known by his 'Vidas de los Españoles célebres' (1807-34). His complete works are published in Rivadevieyra's 'Biblioteca de autores españoles' (Vol. XIX., 1852); and by Rojas (1897-8).

Quintet', a musical composition for five instruments or voices, accompanied or unaccompanied. (1) Quintets for stringed instruments have been written much less frequently than quartets, by reason of their complexity. Boccherini, nevertheless, wrote 125. Among famous string quintets are Beethoven's two in C and E flat, Mendelssohn's in B-flat, and Schubert's in C. There are various quintet combinations, including brass and wood-wind, as Mozart's in E-flat for oboe, clarinet, horn, bassoon, and piano. (2) Vocal quintets are also rare, but very effective. The most notable modern example occurs in Wagner's opera of 'Die Meistersinger.'

Quintilianus, kwīn - tīl - ĭ - ā'nūs, **Marcus Fabius**, Roman rhetorician: b. Calagurris (Calahorra), Spain, probably between 35 and 40 A.D.; d. about 118. He was educated at Rome and about 69 began to practise as an advocate. Subsequently he became a teacher of rhetoric. Domitian bestowed on him the consular rank. His first important treatise, 'De Causis Corruptæ Eloquentia,' is no longer extant. His great work, 'Institutio Oratoria,' was written about 93, and embraces a statement of his theory of education together with a discussion of the principles, scope, and matter of oratory; also its manner under the general term style. The best editions of Quintilian are those of Burmann (Leyden, 1720), Capperonier (Paris, 1725), Gesner (Göttingen, 1738), Spalding and Zumpt (Leipsic, 1798-1829), and Halm (1868-9). There are also special editions of the 10th book, among which are those of Bonnell (1851), Kruger (3d ed. 1888), Peterson (1891); this book criticizes Greek and Latin literature, from the point of view of the orator and its usefulness in forming a vocabulary.

Quintilius, kwīn-tīl'ĭ-ūs, **Aurelius Claudius**, Roman emperor, 270 A.D. He was a brother of Claudius II., and at the latter's death was ele-

vated to the throne, but as the army at Sirmium had elected Aurelian emperor, Quintilius, seeing himself deserted by his followers, committed suicide. He seems to have been a man of unblemished character and to have possessed the high attributes of his brother. The length of his reign is usually placed at 17 days, but the large number of his coins extant indicates that he held the office for some months.

Quin'tuple Alliance. See **QUADRUPLE ALLIANCE**.

Quin'tus Cal'aber, or **Smyrnæus**, Greek poet: belonging probably to the end of the 4th century A.D. His surnames are derived from the discovery of his poem in Calabria (in a convent at Otranto), and his mention of Smyrna as the place of his residence. His poem, *Παραλειπόμενα*, 'Ομήρω, ('Supplement to Homer'), is a continuation of the 'Iliad,' in which he imitates, with very little originality, the poets of the epic cycles. A critical edition of this, by Tychsen, with remarks by Heyne (1807), was published by the Bipont Society. There is also an edition by Köchly (1853).

Quintus Curtius. See **CURTIUS, RUFUS QUINTUS**.

Quip'o, a cord about two feet in length, tight-spun from variously colored threads, and to which a number of smaller threads are attached in the form of a fringe: used among the ancient Peruvians and Mexicans for recording events, etc.

Quir'inal, one of the hills of Rome, not included in the ancient Septimontium, or "City of the Seven Hills," but part of the four regions of the city, and included in the Servian Wall. Next to the Palatine and Capitoline, it is the oldest and most famous part of the city. The temples of Flora, Salus, and Quirinus were on the Quirinal, and also the baths, or the great thermæ, of Diocletian and Constantine. Pope Gregory XIII. began here the erection of a summer residence which was completed by Paul V. Victor Emmanuel took possession of it in 1870, and it has since been the residence of the king of Italy. One of the principal treasures of the palace is the ceiling decoration of one room,—painted by Overbeck (q.v.). The subject is 'The Flight of Pius IX. in 1848.' Other treasures are an 'Annunciation,' by Guido Reni, and several other works of art. See **ROME**.

Quirinus, kwî-rî'nûs, Roman deity, ranking next to Jove and Mars. His origin appears indistinct but he is represented as a war god prepared for battle in times of peace. The third great flamen was assigned to his worship and his temple stood on the Quirinal Hill near the Porta Quirinalis. He was honored by the Coline Salii and a new building was erected in his honor 293 B.C., which after its destruction by fire was replaced with an imposing structure by Augustus 16 B.C. In the 1st century B.C., however, the belief that Quirinus was Romulus raised to the rank of a divinity gained credence and this opinion was favored by Cæsar and Augustus. His annual festival was celebrated on 17 January, the date of the supposed translation of Romulus to heaven.

Quirites, kwî-rî'têz, originally the inhabitants of Cures, a Sabine town, and a name afterward applied to that portion of the Sabines

who at an early period dwelt in Rome. Quirites being applied to them in their civil capacity, while Romani was applied to them in their political and military capacity. On this account it was regarded by the soldiers as a great indignity to be addressed as Quirites, and Julius Cæsar on one occasion quelled a rising mutiny among his troops merely by scornfully haranguing them under the appellation of Quirites. But the contumelious sense of this name had banished before the time of the Augustan age.

Quirk, a term commonly used in architecture and carpentry: (1) A sudden turn; applied to a form of molding in which an acute recess separates the molding proper from the fillet or soffit. It is much used between moldings in Gothic architecture; in Grecian, and sometimes in Roman, architecture ovolos and ogees are usually quirked at the top. (2) A projecting fillet on the sole or side of a grooving plane, which acts as a fence or a gauge for depth or distance. (3) A piece taken out of any regular ground-plot or floor, so as to make a court, yard, etc.; thus, if the ground plan were square or oblong, and a piece were taken out of the corner, such piece is called a quirk.

Quiroga, kê-rô'ga, **Juan Facundo**, Argentine politician and soldier: b. La Rioja, Argentina, 1790; d. near Cordova, Argentina, 1835. He was educated in Spain and on his return to Argentina organized a band of rude soldiery which made him practically the ruler of north-eastern Argentina in 1820. In 1827 he appointed a governor of La Rioja, secured the election of Dorrego as president and though defeated by General Paz in 1830 became governor of Buenos Ayres in 1834. He was assassinated in the following year.

Quit and Goal, in astronomy, two terms introduced by Prof. H. A. Newton, of Yale University, to define the two points opposite each other in the heavens toward one of which the earth is at the time moving in its orbit round the sun and from the other receding.

Quit-claim, in law, a deed of release; an instrument by which some claim, right, or title, real or supposed, to an estate, is relinquished to another without any covenant or warranty, express or implied. See **DEED**.

Quitch. See **COUCH GRASS**.

Quitman, kwit'man, **John Anthony**, American politician and soldier: b. Rhinebeck, N. Y., 1 Sept. 1799; d. Natchez, Miss., 17 July 1858. He studied law and in 1821 removed to Natchez, Miss., where he established a successful law practice. He was elected to the legislature in 1827; was chancellor of the superior court of Mississippi in 1828-31 and in 1832-4; was president of the State senate in 1835; in 1836 served as ex-officio governor of the State and in 1839 was judge of the high court of error and appeals. Interested in the cause of Texan independence he labored earnestly in its behalf, receiving at the outbreak of the Mexican war the rank of brigadier-general of volunteers. He distinguished himself in the battles at Monterey, Vera Cruz, Alvarado, and Chapultepec, was promoted major-general of volunteers and received from Congress a sword and a vote of thanks. He was appointed governor of the City of Mexico by General Scott and on his return was elected governor of Mississippi in 1850, which

office he resigned in the following year when accused of complicity with the Lopez-Cuban expedition, a charge of which he was acquitted. In 1855-8 he served in Congress, where he was an ardent supporter of states rights. Consult Claiborne, 'Life and Correspondence of John A. Quitman' (1860).

Quito, *kē-tō*, capital of the Republic of Ecuador, situated only a few miles south of the equator, but at a height of more than 9,000 feet above sea-level. Climatic results of proximity to the equatorial line are modified and nearly equalized throughout the year by those of altitude; the temperature is, therefore, spring-like. It is, however, an inaccessible inland place; until 1903 (see ECUADOR) neither railway nor highway connected it with the seacoast. A part, at least, of the journey to Guayaquil, 165 miles away, was usually made on mule-back, along a mere bridle-path which crossed the breast of Mt. Chimborazo at a height of 14,000 feet; and the rarefaction of the atmosphere at that altitude can seldom be supported without discomfort. For the transportation of freight from the port to the interior two or three weeks have hitherto been required. Owing to its remoteness and the lack of highways, the city is visited by few strangers, and has no good hotels, no carriages, or wagons. Yet the streets are lighted by electricity, and the list of public institutions devoted to education, the Roman Catholic church, and the government, is quite impressive, including an astronomical observatory, botanical garden, school of agriculture, and other adjuncts of a "central university," with faculties of belles-lettres, science, law, and medicine. The architecture in general is that of a country subject to earthquakes—low and substantial. Features deserving special mention are the beautiful park called the Alameda, and the Sucre Theatre. The estimate of population (probably much too liberal) in semi-official publications is 80,000. See also ECUADOR, *History and Political Divisions*.

Quivira, *kē-vē-rā*, a "province," reputed to have been populous and rich in gold and other things, of which Francisco Vasquez Coronado, the Spanish explorer, received news from a plains Indian, known as the "Turk," while in winter quarters on the Rio Grande in New Mexico in 1540-1. Coronado started from Pecos pueblo in New Mexico, with his army, guided by the "Turk," in the spring of 1541, and after long wandering over the buffalo plains of Texas, sent the larger part of his force back to New Mexico and continued his journey due northward for 35 or 40 days, encountering the first settlement of Quivira about the present Great Bend, Kan. The province was found to consist merely of a group of villages, composed of grass lodges and inhabited by a tribe, recently identified as the Wichitas, which raised corn and hunted the buffalo. Coronado put the "Turk" to death, and after exploring the country for several months, returned by a more direct route to New Mexico. Coronado's disappointment having become forgotten, the name Quivira lingered in the minds of later Spanish explorers of the Southwest and grew to be the watchword of an unexplored Eldorado. After the abandonment of the Indian pueblo of Tabirá, in eastern New Mexico, about 1675, the idea of Quivira and its supposed wealth was transferred to the ruins of the New Mexico

village, and the name "Gran Quivira," then applied to it, has since been popularly retained. Consult Hodge, 'Coronado's March to Quivira,' in 'Brower's Memoirs of Explorations in the Basin of the Mississippi' (1899).

F. W. HODGE,
Smithsonian Institution, Washington, D. C.

Quixote, Don. See DON QUIXOTE: CERVANTES.

Quo Vadis, *kwō vā'dis*, a popular historical novel by the Polish novelist, Henryk Sienkiewicz, published in 1895 and familiar to American readers through the translation by Jeremiah Curtin. It deals with the history of Rome in the time of Nero. Its curious title has reference to an ancient legend, which relates that Saint Peter, fleeing from Rome and from crucifixion, meets his Lord Christ on the Appian Way. "Lord, whither goest thou?" (Domine, quo vadis?) cries Peter. "To Rome, to be crucified again," is the reply. The Apostle thereupon turns back to his martyrdom.

Quoin, *koin* (French, *coin*; Latin, *cuneus*, a wedge), a technical word for a wedge; (1) in artillery, the wedge used to elevate and depress a cannon or other piece of ordnance; (2) in printing, the wedges used to fix pages of type within the chase; (3) in architecture the term is applied to any external angle, but especially to the angular courses of stone projecting beyond the plane surface of the wall at the corner of a building, and specifically designated rustic quoins.

Quoits, *kwoits*, a game somewhat resembling the throwing of the discus among the ancients; only the discus was flat, while the quoit is ring-shaped. (See DISCUS.) The quoits are made of metal, usually iron, and are comparatively thick at the inner edge of the ring, but sharp enough at the outer edge to stick in soft clay when properly thrown. In size they vary from 8 to 9¼ inches. The game is played on a ground from 18 to 24 yards in length, at each end of which a pin called a hob is fixed in the ground to serve for a mark. The object of the game is to throw the quoits from one end of the ground to the other so as to make them stick in the ground as near the hob as possible. The best shot, called a ringer, is when the quoit surrounds the hob. The players are divided into sides, and each player has two quoits, which he delivers in succession. The winning side counts one for each quoit that it has nearer the hob than the nearest of the losing side, and if it has a ringer it counts two for it. The rules as to the size of the quoit, the distance between the hobs, and other particulars, vary with different players. In the United States quoits are generally played with cast-off horseshoes.

Quoratean (*kwō-rā-tē'an*) **Indians**, an American linguistic stock, comprising the Kworatem and Karok tribes, from the former of which the stock derives its name. The tribes occupy Lower Klamath River from the mountains a little above Happy Camp to the junction of the Trinity, and Salmon River from its mouth to its sources, in northwestern California.

Quorum, in old English law, a collective name for those justices of the peace whose presence is necessary to constitute a bench. Also such a number of officers or members of a body as is competent by law or constitution to transact business.

R

R the eighteenth letter of the English and other alphabets derived from the alphabet of the Latins. The corresponding letter of the Greek alphabet, rho, has the form Ρ, ρ, which is the q of the ancient Phœnician alphabet, with the loop turned to the right; in some very ancient Greek Italic inscriptions occurs the form R which was adopted by the Romans. R is classed as a liquid or semi-vowel with *l*, *m* and *n*. Its normal sound is doubtless either the *trill* produced by vibration of the tip of the tongue raised toward the front palate, or the *burr*, which is produced by a vibration of the lower part of the tongue and the uvula; the trill is heard in the speech of the Latin nations—Italian, French, and Spanish; the burr in that of the Germans and Scandinavians. In present English speech the *r* is sounded with a very faint trill or quite without a trill, save in the pronunciation of the people of certain counties of England, who produce it with a guttural vibration; in the pronunciation of this letter by the Scotch and Irish the trill is distinctly heard. When *r* begins a syllable and when it follows a consonant,—as in *vacc*, *trap*, it is distinctly a consonant; but in other situations, as in *nerve*, *hard*, *never*, it is really a vowel sound. In the faulty or affected pronunciation of certain classes *r* becomes equivalent to *w*, for example, *vevy* for very. The two liquids or semi-vowels, *r* and *l*, are sounded when the voice is modified by certain positions of the tip of the tongue relatively to the front palate; hence the two letters are freely interchanged between one language and another and within the vocabulary of one language; Spanish *azul* is English azure; *paralysis* becomes palsy; from *parabola* comes, indirectly, palaver. There are races or peoples who are unable to pronounce the *r* with either the trill or the burr or even with the slight vibration heard in English speech; in such case *l* takes the place of *r*. When in Greek a word or syllable begins with *r* that *r* is always aspirated; and the ancient Romans represented this aspiration by inserting *h* after the *r*; this *h* we retain, though we recognize no difference between the *rh* of *rhabdomancy* and the simple *r* of *rabid*. In many English words the *r* found in their Anglo-Saxon originals is dropped; for example, *spræcan* becomes speak; on the other hand, we insert *r* in words which in their ancient form were without it; for example, Anglo-Saxon *brydguma* becomes bridegroom; and French *cartouche* becomes cartridge.

Ra, rä. See **RE**.

Ra-ma's Bridge. See **ADAM'S BRIDGE**.

Raab, räb, **Johann Leonhard**, German etcher and line-engraver: b. Schwaningen, near

Anspach, Germany, 29 March 1825; d. 1899. He was educated at Nuremberg and at the academy in Munich, and received an appointment as professor of engraving at the latter place in 1860. His work includes engravings after Raphael, Titian, Veronese, Kaulbach, Lessing, Schwind, Ramberg, and others, besides a collection of 50 etchings reproduced from the most notable works in the old Pinakothek at Munich.

Raab (Gvör, dyër), Hungary, capital of a province of the same name, situated at the confluence of the Raab with a minor branch of the Danube, 70 miles southeast of Vienna, a position uniquely advantageous from both a military and commercial viewpoint. Its importance dates from early Roman occupation. A considerable trade is carried on in grain, tobacco, and horses, and in manufactures of woolen cloth and cutlery. In 1809 the combined Austrian-Hungarian forces were defeated here by the French troops under Eugene Beauharnais. Pop. (1900) 28,989.

Rab and His Friends, a short story by Dr. John Brown, an Edinburgh physician, published in 1855. Rab's friends are his master and mistress, James Noble, the Howgate carrier, and his wife Ailie. Perhaps no truer, more convincing dog character exists in literature than that of ugly, faithful Rab. The pathos in the simple lives of himself and his friends is heightened in the tinge of Scotch dialect, as well as by the author's wise self-restraint.

Rabanus, rä-bä'nūs, or **Hrabanus, Maurus**, Carolingian prelate: b. Mayence about 776; d. there 4 Feb. 856. His education was obtained in the cloister school of Fulda, and later at Tour, where his instructor, Alcuin, surnamed him Maurus after the legendary founder of the order of St. Benedict in France. He became the head of the school at Fulda, and in 822 was elected abbot of the monastery. In 842 he resigned and retired to Petersburg, but came again into public life in 847, when he was elected archbishop of Mayence. He was one of the bitterest of the opponents of the monk Gottschalk, the originator of the predestination controversy in the 9th century. His literary activity was considerable, resulting in commentaries on the Old Testament, on the Gospels of St. Matthew and St. John, and the Pauline Epistles, devotional books, homilies, hymns, polemics, and a Latin-German Glossary to the Bible. His 'Opera Omnia' are comprised in Migne's 'Patrologiæ Cursus Completus,' reprinted from Colverino, edition of 1627. This edition contains his life by the monk Rudolph, and by Johann Trithemius. Consult studies by Spengler (1856), Köhler (1870), Richter (1882).

Rabât, rä-bât (RIBÂT'), or **Abbât**, also known as **NEW SALLEE**, Morocco, in the prov-

ince of Fez, on the Atlantic coast, 62 miles west of Mequinez. It stands on a rocky plateau, and is surrounded by massive reddish-brown fortifications. A conspicuous feature from the sea is the Hasan Tower, a minaret 180 feet high, the remnant of an ancient mosque. Rabât's manufactures are carpets, woolen, cotton, and leather goods. The Sallee pirates formerly built their ship at Rabât. Pop. 30,000.

Rabba, räbä, Sudan, in the kingdom of Gando (Northern Nigeria), on the left bank of the Niger; carries on an active trade in slaves, and ivory, and woolen goods. Pop. about 40,000.

Rabbi, a title of honor among the Hebrews; "my teacher," "master." John expressly states that the word was equivalent to "teacher" (Greek, *didaskalos*, rendered in the Authorized Version "master"; John i. 38). There is another form of title, *rabboni*, found in the New Testament. The form rabban, the Chaldaic form of the Hebrew "rab," was considered the most honorable, and was only applied to seven persons. Rabbi was also looked upon as a higher title than rab. It is supposed that this title first came into use at the period immediately preceding the birth of Christ. In the time of our Lord it was applied generally to all religious teachers, and hence sometimes to Christ himself. Now the term rabbi is applied to regularly appointed teachers of Talmudic Judaism. Since 1831 these have in France been salaried by the state. Their duties are not only to give instruction in the Talmud, but also to draw up deeds of marriage and divorce, to examine butchers, and to give their opinion as to what is legal and what is illegal in the Jewish ritual.

Rabbinical Language, that form of Hebrew in which the Jewish scholars and theologians of the Middle Ages composed their works. See JUDAISM—HEBREW LANGUAGE, JEWISH LITERATURE; etc.

Rabbinical Learning and Literature. See JUDAISM—JEWISH LITERATURE; HEBREW LANGUAGE; JEWISH PHILOSOPHICAL WRITERS; etc.

Rabbinical Legislation. See JUDAISM—THE SPIRIT OF RABBINICAL LEGISLATION.

Rabbit, a name when properly used, restricted to a single species (*Lepus cuniculus*) of the rodent family, *Leporida*, to which the native American hares (q.v.) also belong. The rabbit is of European origin, and, although found wild in many places, is better known in the domesticated or semi-domesticated state in which it has been introduced into the United States. Although the habits of the rabbit afford the best distinction from the hares, the wild species exhibits some structural characteristics, among which are its generally smaller size, the shorter ears of uniform brown color, and the shorter limbs. The hind legs in the hares are proportionally longer than in the rabbits, and the eyes are larger and more prominent than in the latter animal. The face is also narrower and the skull lighter in the rabbit. The rabbit's fur in its native state is of a nearly uniform brown color, while under domestication the color may become pure white, pure black, piebald, gray, and other hues. The texture of the fur also changes under domestication.

Unlike the hares, which construct only simple nests or forms, the rabbit lives permanently in underground burrows, large colonies of which are often to be found in some dry sandy bank overgrown with furze or brush, or other similar locality. Such "warrens" are often specially set apart for them in order that they may breed and multiply for the market, their flesh being excellent as food, and their fur and skins of value. The burrows are irregularly disposed, and communicate freely with each other. Rabbits are extremely prolific, and begin to breed when about six months old. They may breed six or eight times a year, producing from five to seven or eight at a birth.

The parturient rabbit excavates a special burrow or tunnel for herself in which to give birth to and shelter her progeny, the nest being lined by down plucked from her own body. The young are hairless when born, and have their eyes closed. The eyes open about the tenth or twelfth day. These animals feed on tender grass and herbage, and sometimes do great damage to young trees by stripping them of their bark.

These animals grow exceedingly tame and domesticated, and may exhibit no small degree of intelligence. They are snared, taken by ferrets and nets, or may be shot. Rabbits are subject to certain diseases, such as rot, parasitic worms, and a kind of madness. The original home of the rabbit is believed to have been those parts of Europe and Africa around the western half of the Mediterranean, where it still abounds, but it is now widely spread throughout temperate western Europe, and has been conveyed by man to such distant lands as Australian colonies, Tierra del Fuego, and the Falkland Islands. In Australia and New Zealand it has multiplied so enormously as to have become a serious pest to the colonists, causing immense loss and damage by eating up the pasture intended for sheep and cattle. Various methods of extermination have been tried against them, but as yet none have had more than a moderate success. Large numbers are now killed and exported as food, frozen or otherwise preserved, and millions of skins are annually shipped to Europe and the United States. In some parts of South and Central America, and especially in Jamaica, the domestic rabbit has been introduced and established in the wild state. Darwin records several cases where quite distinct races of rabbits have resulted from their isolation on islands. An Asiatic species (*L. hispidus*) is closely related to the European rabbit, and a so-called tailless rabbit (*Romerolagus*) has recently been described from the region of Mount Popocatepetl in Mexico. It is peculiar in the possession of well-developed clavicles. All the domestic breeds of rabbits appear to have been derived from the feral species of southern Europe; and have been but little influenced by occasional crosses with hares. The Chinese, as early as the time of Confucius, appear to have bred rabbits for sacrificial purposes; and domesticated varieties are mentioned in classical Greek and Roman writers. The most noteworthy change under domestication has been the great increase in size and weight, the latter having been raised from

3 pounds in the wild rabbit to as much as 18 pounds in the Flemish giant. This variety is bred chiefly for food, but for this purpose is less esteemed than the Belgian "hare," so-called because of its large size and hare-like color, and the unfounded belief that it originated from a cross between the hare and rabbit. The qualities which recommend the Belgian variety for market breeding are its extreme fecundity, the ease with which it may be kept in confined quarters, its rapid growth, so that it is ready for eating in about four months after birth, and the similarity of flavor of the young to the wild rabbit. A wave of enthusiasm for Belgian hare breeding passed through this country a few years ago, but has largely subsided, though many large rabbitries continue to supply the cities, particularly in the west. Of the purely fancy varieties the lop-ear is the most remarkable; the external ears in fine specimens measure 23 or even 24 inches long and 6 inches wide. The Angora, which originated in Asia Minor, has the beautiful long, silky white hair peculiar to several animals of that region, and there and in parts of Europe is bred for its hair, which is clipped and woven into underclothes, etc. Other varieties are peculiar chiefly in color. For methods of breeding, etc., consult Knight, 'The Book of Rabbit,' (London, 1889); Rayson, 'Rabbits,' (London, 1880); Carnegie, 'Practical Game Preserving'; for history, variations, habits, etc., Darwin, 'Animals and Plants under Domestication', Vol. I. (New York, 1868); Palmer, 'Jack Rabbits of the United States', (Washington, 1896); Reports of the Royal Commission of Inquiry on the Extermination of Rabbits in Australasia, especially that of 1890.

Rabbit-fish, in the Southern United States, a globe-fish (q.v.) of the genus *Lagocephalus*. In Bermuda and other islands of the Middle Atlantic, a common market-fish, caught in deep water. It is a rather large, reddish crown őscolar (*Promethichthys prometheus*), and owes its name to its prominent front teeth.

Rabelais, François, frän-swä räb-ë-lä, French author; b. Chinon, Touraine, 1483; d. Paris 9 April 1553. He entered the Franciscan order at Fontenay-le-Comte, in Poitou, and being at first freely permitted to study, acquired Arabic, Hebrew, and Greek, and read omnivorously on almost all subjects. Eventually, however, the Franciscans came to distrust the new learning, Rabelais was deprived of his books, and in disgust fled the monastery. Shortly afterward he obtained permission of Clement VII. to enter the Benedictine order, but in no long time quitted this brotherhood also, and began to traverse the country under the habit of a secular priest. His biographers have found it difficult to follow him during this period of his life, but it seems that in his wanderings he cultivated all the sciences of the day, and especially philology, with assiduity, and that in this he exhibited powers of acquisition such as few have possessed before or since. In 1530 he was enrolled as bachelor in the faculty of medicine at Montpellier, where he lectured in 1531-2, although it was not till 1537 that he obtained the degree of doctor. In 1532 he went to Lyons, where he published 'Hippocratis et Galeni Libri Aliquot' (1532), and the first germ of his 'Gargantua' (1532), of which, according to his own account, more copies were sold in

two months than of the Bible in nine years. He was made physician to the Lyons Hospital, and was a member of the Société Angélique, a coterie of scholars that had gathered around the workshop of Gryphius, the printer. This first specimen of the power of Rabelais in the style that has rendered him famous has all the grotesque humor, amounting even to buffoonery, and the variety of marvelous adventures of his later works of the kind, but wants the delicate railery, the sustained allegory, and profound philosophy, which most students of Rabelais find in the subsequent versions of 'Gargantua,' and still more in the last three books of 'Pantagruel.' The first part of 'Pantagruel' appeared under the anagrammatic pseudonym of Alcofribas Nesier, within a year or so after the first work, and its success was such that it passed through three editions in one year. In 1534 he accompanied, probably as physician, Cardinal Jean du Bellay, on an embassy to Rome. Not long after he is found again at Lyons, where the 'Gargantua,' as we now have it, first saw the light in 1535. In 1536 he was again at Rome, and on this occasion obtained from the Pope absolution for having neglected to enter a Benedictine house and other delinquencies. In the year following he is known to have been practising his art at Paris, but his love of wandering had not yet ceased, and his place of abode for the next eight or nine years was as unsettled as it had been during any previous part of his life. In 1546 he was probably in Paris, when the third book of his 'Pantagruel' appeared. In this the fantastical and trivial adventures that crowd the previous books give place in a great measure to regular dissertations, in which all the great moral and social questions of the day are discussed with the gaiety and irony peculiar to Rabelais, and with a freedom that roused the suspicion of the clergy, who endeavored to have it suppressed. The favor of the king secured the free publication of this book, but it was with more difficulty that a license was obtained for the fourth book from the next king (Henry II.), who had succeeded Francis in 1547. A mutilated edition of this appeared surreptitiously at Lyons in 1547. The license to publish was not obtained till 1550, and it was only in 1552 that a complete and authentic edition of the book appeared. Rabelais was installed in the cure of Meudon, which he had had bestowed on him by his former patron, Jean du Bellay, and here he seems chiefly to have resided during the remainder of his life, resigning two months before his death. He left at his death the whole of the fifth book of 'Pantagruel' in manuscript. A sixth book was intended to be added, but there is only a fragment of it indicating its subject, 'Les Noces de Panurge.' His enemies busily pointed out impieties, and he once fled to Metz to escape danger. Rabelais was one of the first to give flexibility and finish to the yet rude and harsh language of his country. Boileau calls him *La raison en masque*, and Rousseau, *Le gentil maître François*. His house was the resort of the learned; his purse always open to the needy; and his medical skill employed in the service of his parish. His work cannot now be easily understood without a glossary and commentary. It has been widely regarded, especially in France, as a treasury of wisdom, wit, and shrewd sense.

DOMESTIC RABBITS

1. Wild Rabbit. 2. 3. French Rabbits. 4. French Lop-Ear. 5. Norman Rabbit. 6. Angora Rabbit.

and 'Pantagruel' may be mentioned that of Le Duchat (1711); the Variorum edition (1823-26); a splendid edition, illustrated by Gustave Doré (1858); a one-volume edition by Louis Barré (1864). Four volumes of a fine edition of his complete works, with notes and a glossary by Marty-Laveaux, appeared at Paris in 1868-81. There are English translations by Urquhart and Motteux (1653-94; new edition 1892), and W. F. Smith (1893). Consult: Besant, 'Rabelais' (1879); Besant, 'Readings in Rabelais' (1881); Stapfer, 'Rabelais, sa Personne, son Génie, son Œuvre' (1889); Gebhart, 'Rabelais, la Renaissance et la Réforme' (1895).

Rabies. See HYDROPHOBIA.

Rabshakeh, rāb-shāk'ē, an officer of the king of Assyria, mistaken in the Authorized Version of the Bible for a proper name, but in fact an official title, probably that of a military commander. He is sent with Tartan and Rab-saris, also titles of high officials, to take a threatening message from Sennacherib to King Hezekiah. He delivers it in the Hebrew tongue, and when requested to use the Aramaic dialect, the language of diplomacy, so as not to alarm the people, he insolently refuses. (2 Kings xviii.-xix.; Isaiah xxxvi.-xxxvii.)

Raccoon', the name, of Indian derivation, given to the typical members of the *Procyonidae*, a family of carnivorous mammals, resembling the bears in their plantigrade feet and other characters, but differing from them especially in the long tail, sharp snout, slender body, and moderate size. All of the five or six known genera are confined to America, though the related Asiatic genus *Elurus* is now placed here. (See PANDA.) The members of the typical genus *Procyon* possess six incisors, two canines, eight premolars, and four molars in each jaw, and the group is well exemplified in the common raccoon (*Procyon lotor*) which derives its specific name of *lotor*, "a washer," from its habit of washing its prey before eating it, or of holding the food in the fore paws and shaking it violently backward and forward in the water so as to moisten and saturate it as thoroughly as possible. The raccoon is a heavily built animal, about three feet long, with a pointed snout, short ears and bushy tail alternately ringed with black and white. The general body color is a sooty or blackish-gray, and the fur consists of a close set of under hairs, with larger outer hairs, the latter being marked black and white. The upper part of the head and the portion across the eyes are colored dark brown. Throughout most of the United States the raccoon is abundant, and on the Pacific side reaches from Alaska to Central America. In spite of the settlement of the country and much persecution it generally holds its own, and in many sections is actually increasing in numbers. These animals, although typically carnivorous, yet seem to feed largely upon, and indeed to prefer, vegetable matters. In the natural state their food consists of all kinds of small birds and their eggs, mice, reptiles, frogs, crayfish, mussels, oysters, nuts, fruits, etc. Occasionally they catch fish or clear out a hen roost, and their frequent depredations upon fields of corn, of which they are very fond in the milk stage, has gained them the enmity of farmers. They are, as already remarked, fond of moisture and water. The German name, *Waschbär*, or "washing-bear," is

given to the raccoon for the same reason as that indicated by the specific name *lotor*. Raccoons are among the most strictly nocturnal of American mammals, and spend the day in sleep, usually in a hollow limb or tree trunk. During the winter they pass into an intermittent state of hibernation. About April four to six young are born, which remain with the parents for a year or more, forming the small parties in which these animals are usually found. The raccoons are much hunted by means of dogs, which force the animal to take refuge in a tree, whence it is dislodged by climbing. The subtlety and cunning displayed by these animals in their endeavors to escape have become quite proverbial—expressions such as "sly 'coon," "wake as a 'coon," indicating these qualities. They are, however, very easily trapped, and when taken young make very gentle and interesting pets. They use their fore paws almost as expertly as a monkey its hands, and their great curiosity prompts them to investigate everything which attracts their attention. The agouara or crab-eating raccoon (*P. cancrivorus*) is found throughout South America. It is generally larger than the common species, the tail being shorter, of a grayish-yellow tint, and marked with six black rings. The fur is blackish-gray, tinted with yellow, and of variable lights and shades over the different regions of the body. The eyes are surrounded by dark-brown patches, which run into the ears, and terminate in a patch on the top of the head. Although denominated "crab-eating," it does not appear to be specially addicted to this dietary.

Related genera are *Bassaris*, of which *B. astuta* extends from Mexico into the southwestern United States, *Nasua*, the curious arboreal coatis of Mexico and South America, and *Cercoleptes*, represented by the Central and South American kinkajou, which has a long protractile tongue. Consult: Stone and Cram, 'American Animals' (New York, 1902); and Beddard, 'Mammals' (London, 1902).

Raccoon-dog, a small wild dog-like animal (*Nyctereutes procyonides*) of eastern China and Japan, much resembling a miniature raccoon in appearance, especially about the head. It lives in burrows, gathers most of its food (fish, crabs, etc.) along the banks of rivers, and is frequently kept in captivity, especially among the Japanese, who also value its fur and eat its flesh. Its fur is long and grizzled, but handsome; its muzzle sharp, ears short, and tail short and bushy. Consult Mivart, 'Dogs, Jackals, Wolves, and Foxes' (1890).

Raccoon-oyster, a name in the Southern States for the small irregular wild oysters, growing numerously in the salt marshes, and much eaten by raccoons and other animals.

Race, Cape. See CAPE RACE.

Raceme, rā-sēm', in botany, a form of inflorescence in which the primary axis is elongated, and bears flowers placed on pedicels of nearly equal length, as in the currant. A raceme differs from a spike only in the flowers being stalked, instead of being sessile. See FLOWER.

Racer, or **Blue Racer**, a blacksnake (q.v.) especially the common lowland one (*Zemmis constrictor*), so called from its swiftness.

RACHEL — RACINE

Rachel, in Bible history, the second daughter of the Aramaic cattle-owner, Laban. Jacob obtained her as wife by devoting 14 years to the service of her father. At the end of the first seven years he found in his veiled bride not the Rachel promised, but Leah, her elder sister, whom he did not love, and was obliged to serve seven years more in order to gain Rachel. She was the mother of Joseph and Benjamin. Her so-called tomb stands to this day on the road between Jerusalem and Bethlehem and is held in the highest veneration by both Jews and Mohammedans.

Rachel, rä-shël (ELISA RACHEL FÉLIX), French tragédienne: b. Munt, Canton of Aargau, Switzerland, 24 March 1821; d. Le Cannet, Provence 3 Jan. 1858. Her father was a German Jew, naturalized in France, and after much wandering about Europe established his family at Lyons, where the two oldest children, Sarah and Rachel, sang and begged in the street to help out the family support. About 1830 they removed to Paris and the two girls sang on the Boulevards until discovered by Etienne Choron, teacher in the School of Sacred Music, who undertook to teach them singing. Rachel's voice was found to be too harsh for this, and in 1834 Choron induced his friend, Pagnon Saint Aulaire, to train her for the stage. On the advice of M. Sanson she entered the Conservatoire, where, however, her harsh voice and small stature seemed at first against her. She made her debut in a play called 'La Vendéene' at the Gymnase, 1 May 1837. The next year she joined the company of the Theatre Français and made her first appearance as Camille in Corneille's 'Les Horaces' 12 June 1838. She appeared in several parts successively and finally repeated in September her performance of Camille, was seen and applauded by the powerful critic of the "Debats," Jules Janin, and her position established. After appearing in other parts in the French classic drama with increasing success, she visited England in 1841 and again in 1842, repeating her triumphs there. Later while still supreme at the Theatre Français she made visits to other European cities, and in 1855 appeared in America. Here her success was only moderate, owing to her unfamiliarity with the language. A severe cold caught during her American tour ended in a consumption, from which she died at Le Cannet in the south of France. Her great reputation was made in five or six roles of the ancient classic drama of France, of these Phèdre being accounted her greatest. In the course of her career she created 13 modern roles, written for her, 'Adrienne Lecouvreur,' alone of these still holding a place on the modern stage. She appeared in several other modern roles that had been acted before her representation. Consult: *Memoirs* by Madame De B— (1858); Janin, 'Rachel et la Tragedie' (1858); Kennard, 'Rachel' (1888).

Rachi'tis. See RICKERS.

Racine, Jean Baptiste, zhõn bã-těst rä-sën, French dramatist: b. La Ferté-Milon, Picardy, 21 Dec. 1639; d. Paris 21 April 1699. He studied at the College of Beauvais, and subsequently at the Port-Royal Institution, where, under the care of Lancelot and Lemaistre, he became a profound Greek scholar. In 1658 he left the

Port-Royal, and began the study of philosophy at the Collège d'Harcourt. To this period belong his first literary efforts, an ode called 'Nymphes de la Seine,' composed in honor of the king's marriage, and for which he was rewarded by Chapelain, then the dispenser of the royal bounty; and two comedies, now lost. About the same time he became intimate with La Fontaine, and this intimacy was so far from tending to make his life more regular, that those of his relations who took most interest in him, and who had destined him for the church, began to be anxious about his prospects. In 1661 he went to live with an uncle, a canon-regular and vicar-general of the cathedral at Uzès (department of Gard), whose influence it was expected would suffice for procuring him a benefice. In this last particular they were disappointed; and at the end of about two years, during which Racine had been vainly endeavoring to study theology, he returned to Paris and the world. In 1663 he was presented at court, and soon made the acquaintance of Boileau and Molière, and began to write for the stage. His first tragedy, the 'Thébaïde,' or 'Les Frères Ennemis,' was first performed by Molière's troupe at the Palais-Royal in 1664, as was also his next, 'Alexandre,' in 1665. But his devotion to the drama did not deprive him of all chance of ecclesiastical preferment, for in 1667 he received the priory of Espinay, and afterward the livings of Saint-Jacques de la Ferté and Saint-Nicolas de Chésy. The drama, however, continued for many years to be his sole serious occupation. His first two tragedies were merely tentative pieces, containing but few indications of the author's dramatic genius. His first master-piece was 'Andromaque,' which on its performance in 1667 produced a profound impression and excited well-merited admiration. It was brought out at the Hôtel de Bourgogne, Racine having in the meantime quarreled with Molière. The immediate successor of 'Andromaque' was a comedy (Racine's only extant comedy), 'Les Plaideurs,' a witty and delightful imitation of the 'Wasps' of Aristophanes. It appeared in 1668, and was at first rather coldly received, being indeed saved only by the laughter of the king. His next pieces were 'Britannicus' (1669); 'Bérénice' (1670), composed at the request of Henrietta of England, who had also invited Corneille to write a drama on the same subject; 'Bajazet' (1672); 'Mithridate' (1673); 'Iphigénie' (1674), considered by Voltaire the greatest work that the French stage has produced; 'Phèdre' (1677), the last piece that Racine produced expressly for the theatre. Little is known of the private life of Racine during this period, almost all his correspondence having been burned from a too pious respect for his memory. In 1673 he obtained a seat in the French Academy. In 1675 he was nominated by Colbert a royal councillor and treasurer of France for the general government of Moulins (Bourbonnais), but never entered on the duties of his office. His withdrawal from the theatre in 1677 was partly due to chagrin at the success of a hostile party of theatrical critics who set up for being fine wits, and applauded one Pradon, a writer now never heard of, at the expense of Racine. Soon after (1678) he was appointed, along with Boileau, historiographer to the king, whom he accompanied in his campaign to

Flanders. After a silence of 12 years Racine, at the solicitation of Madame de Maintenon, added two other pieces to the list of his dramatic works — 'Esther' (1689) and 'Athalie' (1691), the latter often spoken of by French critics as the most perfect of his works. They were both intended for the pupils of Saint-Cyr, the institution founded by Madame de Maintenon. The death of Racine is said to have been hastened by grief at losing the favor of the king. As a dramatist Racine is usually considered the model of the classical or national tragic drama of the French, and in estimating his powers in this field it is necessary for the critic to take into account the stiff conventional restraints to which that drama is subjected. What Racine achieved within these limits is extraordinary. He added to the conventional drama as he received it a grace of which one would not have deemed it capable; he was greater as a poet than as a dramaturgist, and wrote in a style of finished perfection and distinction, developing French versification to its ultimate of rhythm and dignity. In his restraint, proportion, balance, he is rightly regarded as classic. "Perhaps it would be no exaggeration to assert," says Dowden, "that grandeur and beauty are nowhere else so united in French dramatic art as in 'Athalie.'" Besides his dramas Racine wrote several stinging epigrams, some odes and hymns, an abridgment of the history of Port-Royal, letters, and historical fragments on the campaigns of Louis XIV. Among his letters are two in reply to a work of Nicole of the Port-Royal, entitled 'Les-Visionnaires' (1666), in which the author bitterly denounces poets and still more dramatic writers. The tone of these letters is severely sarcastic, and naturally caused great offense to his old friends and masters. Only one of the letters was published at the time they were written, the other after his death. After his retirement from the theatre Racine found it easy to reconcile himself with his old friends. Among the editions of the 'Œuvres Poétiques' of Racine, one of the best is that published at Paris in three volumes (1801-5), regarded as a marvel of typography. An excellent edition of 'Œuvres Complètes' was published in 1865-73 in Hachette's collection of the 'Grand Ecrivains de la France,' preceded by an admirable essay on Racine and his time by Paul Mesnard. There is an English metrical translation by R. B. Boswell (1889-91). Consult also the study by Monceaux (1892, in the 'Collection des Classiques Populaires'); Stendhal, 'Racine et Victor Hugo' (1887); Sainte Beuve, 'Port Royal' (4th ed. 1878).

Racine, Louis, French poet and critic, son of Jean Racine (q.v.): b. Paris, France, 2 Nov. 1692; d. there 29 Jan. 1763. He attained considerable attention as a poet and critic though manifestly under a disadvantage as the son of so eminent a father. His poems 'La Grâce' (1720) and 'La Religion' (1742) were highly praised and the latter ran through 60 editions. He wrote in prose: 'Reflections upon Poetry'; 'Memoirs of the Life of Racine'; and 'Remarks on Racine's Tragedies.' His complete works were published in 1808.

Racine, Wis., city, county-seat of Racine County; on Lake Michigan at the mouth of Root River, and on the Chicago, M. & St. P., and the Chicago & N. W. R.R.'s; about 22 miles

south of Milwaukee and 65 miles north of Chicago. It has steamboat connections with all the lake ports, and electric lines extend to all the nearby towns. It is 40 feet above the surface of the lake, and 690 feet above sea-level. It was settled in 1834; in 1843 was incorporated as a village, and in 1848 was chartered as a city. Racine has a good harbor, one of the best on the lake. It is the commercial and industrial centre of a productive agricultural region about midway between Milwaukee and Kenosha. The chief manufacturing establishments are knitting mills, machine shops, flour and lumber mills, carriage factories, foundries, boot and shoe factories, tanneries, valise and trunk factories, steel spring works, hosiery mills, furniture factories, breweries, plating works, and woolen mills. The products from other manufactures are, bedding, men's clothing, paints, mangles, fanning mills, windmills, bicycles, bits, sheet iron, brass and copper goods, iron specialties, malted milk, chemicals, soap, and other articles. The manufacturing interests are increasing; it is (1904) the second city in the State in the value of its manufactures. In 1903 the capital invested in manufactures was nearly \$18,000,000; and the value of the output was over \$14,000,000. The prominent public buildings and institutions are, the government building, which cost originally \$100,000, the county court-house, the municipal buildings, Saint Luke's Hospital, Saint Mary's Hospital, Taylor Orphan Asylum, and the Dominican convent. The educational institutions are Racine College (P.E.), founded in 1852, the Racine Grammar School (P.E.), Saint Catharine's Academy (R.C.), a public high school, public and parish schools, a public library, which contains about 9,000 volumes, two libraries connected with Racine College, and the Y. M. C. A. library.

The government is administered under a revised charter of 1891, which provides for a mayor, who holds office two years, and a council. The mayor appoints, subject to the approval of the council, the members of the school board. Pop. (1890) 21,014; (1900) 29,102.

Racing. See HORSE-RACING.

Rack, an instrument of torture in frequent use in the Middle Ages, and down to a comparatively recent period. It is not known to have been used in the American colonies settled under British rule, but it is among the ancient instruments of torture preserved at Montreal as relics of French rule in that country. The rack consisted of a large, open, wooden frame, within which the person to be tortured was laid on his back on the floor, with his wrists and ankles fastened by cords to two rollers at the ends of the frame. These rollers were then drawn or moved in opposite directions till the body rose to a level with the frame. Interrogations were then put, and if the prisoner refused to answer, or if his answers were not considered satisfactory, the rollers were further moved, until at last the bones of the sufferer were forced from their sockets. The rack was also used simply for purposes of punishment, apart from desire to extort a confession.

Rackets, or **Racquets**, a game played in a prepared court, open or close, with a small hard ball and a kind of bat. The bat is about two feet in length, about two thirds of which forms

the shaft or handle, the remainder being an oval frame on which is tightly stretched a net-work of cat-gut. The part of the shaft by which the bat is held is covered with leather and ribbed, to enable the player to grasp it firmly. It is from this bat and the net-work, which is its principal feature, that the game derives its name (Italian, *racchetta*, for *retichetta*, an old diminutive of *rete*, Latin and Italian, a net; French, *raquette*). The close, that is, roofed court, is now generally preferred for playing in. It is an oblong rectangular space, and when of full dimensions is 80 feet long, 40 feet broad, and has walls 40 feet high. The players stand facing one of the narrow walls, which is called the front wall. Two horizontal lines are drawn across the front wall, one two feet two inches, and the other, the out or service line, eight feet above the floor. The surface between the floor and the lower of these lines is covered with wood, which serves as a sounding-board to enable the players to know when it is struck by the ball.

The game may be played either single or double, that is, with either one or two persons on each side. It is decided by lot which side goes in first, and when there is only one player on each side the first player assumes which side of the court he pleases (usually the right), while the other stands in the opposite corner. The first player then begins to *serve*, in doing which he must have one foot in the service box of his side. Service consists in striking the ball with the bat so as to make it strike the front wall above the out line without previously striking any other part of the court, and then rebound into the opposite corner beyond the short line. In rebounding from the front wall it does not matter whether the ball strikes either of the side walls or not before it lights on the floor in the opposite corner of the court. If the ball is properly served the second player must strike it before it has made a second bound, so that it strikes the front wall above the board; but in returning the ball in this manner the player may if he likes first make it strike either of the side walls. The player to whom a ball is served does not require to wait till the ball has bounded from the floor before he returns it. He may if he likes return it before it touches the floor. Such a stroke is called a volley. The ball being thus returned by the second player, the first player returns the ball in the same way, and this goes on until either player fails, which may happen in three ways, either by the ball being made to hit the sounding-board, or being struck into the roof or gallery, or later than the first bound. If it is the first player who fails, his hand is out, and it is then the turn of the second player to serve. If it is the second player, then the first scores one (an ace), and the first continues to serve, but goes to the opposite side of the court. The other details of the game must be derived from the rules drawn up by the different racket clubs.

Racovian Catechism, the catechism of Rakow, Russia, where it was originally printed and published. It contained a popular exposition of Socinianism. There were two such catechisms, a smaller and a larger, both afterward published in Germany by Smalcus, the former in 1605, the latter in 1608. In 1652 John Biddle translated the larger of the two into English.

Radcliffe, rād'klif, Ann Ward, English novelist: b. London 9 July 1764; d. there 7 Feb. 1823. She was married at 23 to William Radcliffe, afterward editor and proprietor of the weekly called 'The English Chronicle.' Her first work was 'The Castles of Athlin and Dunbayne,' a Highland story (1789). It had little success, but perhaps as much as it deserved. 'A Sicilian Romance' (1790) is superior to it, and 'The Romance of the Forest' (1791), a still further advance, was dramatized and translated into French and Italian. Her master-piece is considered to be 'The Mysteries of Udolpho' (1794), which was long very popular. The last of her novels published during her life was 'The Italian' (1797), dramatized as 'The Italian Monk,' and translated into French by Morellet. A posthumous romance, 'Gaston de Blondville,' was edited by T. N. Talfourd in 1826, together with some poems. Another work of hers was 'A Journey through Holland and Germany' (1795). Mrs. Radcliffe's novels were at one time very popular. She had considerable power in the description of scenery, and well understood how to excite and maintain the curiosity of her readers. She was perfect mistress of the mysterious in romance and the first English writer of note to introduce descriptions of scenery into fiction. Consult: Beers, 'English Romanticism' (1898).

Radcliffe, John, English physician: b. Wakefield, 1650; d. London 1 Nov. 1714. He was educated at Oxford and there began the practice of medicine, but removing to London in 1684 soon established a large practice which he maintained, it is said, more by his witty conversation than his medical skill. In 1686 he became physician to the Princess Anne of Denmark, and frequently attended William III., after his succession. His bluntness of speech lost to him the favor of Princess Anne and later of King William, though he continued to number many of the nobility among his patients and prescribed for Pope and Swift. His learning was often depreciated; but he seems to have been an acute observer of symptoms and his immense practice gave him a wide field for observation. By his will property was left in trust for the foundation of two medical fellowships, and for the purchase of perpetual advowsons for members of University College. He also left money for the erection of various public buildings, among which was £40,000 for the public library in Oxford, since called the Radcliffe Library. From estates left in trust to the executors to administer for charitable purposes according to their judgment were built the Radcliffe Infirmary, the Observatory at Oxford, and enlargements to St. Bartholomew's Hospital. Later money was granted toward the buildings of the College of Physicians in London, the Oxford Lunatic Asylum and St. John's Church, Wakefield.

Radcliffe, England, in the county of Lancashire, seven miles northwest of Manchester, on the River Irwell. The ancient parish church of St. Bartholomew dates from the time of Henry IV. There are cotton and calico works, bleach-fields, and extensive collieries in the vicinity. Pop. (1901) 25,350.

Radcliffe College, a college for the education of women, affiliated with Harvard University, Cambridge, Mass. Its forerunner was the

Society for the Collegiate Instruction of Women, organized in 1879 to provide systematic instruction for women by professors and instructors in Harvard. This Society was incorporated three years after its organization, and its educational work proved so successful that in 1894 it was formally affiliated with the University. At that time the name of the Society was changed to Radcliffe College, power to grant degrees was conferred, and the president and fellows of Harvard University were constituted the board of visitors of Radcliffe, which should have supervision over the administration of the affairs of the college, the granting of degrees, the appointment of instructors, etc. All diplomas given by Radcliffe are countersigned by the president of Harvard and bear the University seal. Most of the courses of study are identical with the Harvard courses, and graduate students are admitted to some of the graduate courses of the University. The courses are divided into three groups in the different branches of study: (1) courses primarily for undergraduates; (2) courses for graduates and undergraduates; (3) courses primarily for graduates. Courses in Semitic languages and history, history and theory of education, pedagogy, and the history and theory of art and music, are included in the curriculum. The degrees of A.B. and A.M. are conferred. There are two fellowships, one for the promotion of the study of Greek history, literature, art and archæology of the American School at Athens, and one for the promotion of the study of social problems at a settlement house in Boston; there are also eleven scholarships. The college has laboratories of physics, chemistry, zoology, and botany,—the library numbered 18,700 volumes in 1904; the University library and museums are also opened to students of Radcliffe; in 1903-4 a new hall with auditorium, club rooms, etc., was in process of construction. The students in 1903-4 numbered 443 and the faculty 108. Le Baron Russell Briggs of Harvard University was appointed president in 1903.

Radecke, rä-dë-kê, **Robert**, German composer: b. Dittmannsdorf, Silesia, 31 Oct. 1830. He was educated at the Conservatory of Leipzig and in 1853 became musical director of the Stadt Theatre of Leipzig. He afterward served for a year in the army and then settled in Berlin where he engaged as second violin in Laub's quartet and in 1858-63 conducted choral and orchestral concerts with much success. In 1863 he was appointed musical director of the Royal Opera and in 1871 was made royal Kapellmeister for life. He was the successor of Haupt as director of the Royal Institute for Church Music in 1891. Radecke excels as a performer on pianoforte, organ, and violin, but his greatest talent is shown in his compositions, which include about 100 songs, the operetta 'Die Mönkgüter'; overtures, 'König Johann'; 'Am Strande'; etc.

Radegun'da, **Saint**, Frankish queen: b. Thuringia, Germany, 510; d. Tours, France, 13 Aug. 587. She was the daughter of the heathen Berthar, king of the Thuringians, and was carried off prisoner when a child after the victory of Clothaire, king of the Franks, over her father. She was eventually converted to Christianity and married to Clothaire (538). In 553 she took the veil, founded the monastery of

Sainte Croix at Tours, and made her dwelling there. Her life was written by her contemporary and friend, the famous poet, scholar and bishop, Venantius Fortunatus (q.v.). Consult: Bus-sierre, 'Histoire de Sainte Radegonde' (1864).

Radetzky, rä-dët'skê, **Johann Joseph Wenzel Anton Fritz Karl**, **COUNT**, Austrian military officer: b. Trebnitz, Bohemia, 2 Jan. 1766; d. Milan, Italy, 5 Jan. 1858. He joined the Austrian army in 1784, served in the campaigns against the Turks in 1788-9, in 1809 became lieutenant field-marshal and served with ability at Aspern and Wagram. After the peace of Schönbrunn he was appointed a member of the state council of war. In the war with France he fought at Kulm and Leipsic in 1815, and in 1831 was made commander of the Austrian troops in Italy. He was created field-marshal in 1836 and in 1848-9 he crushed the revolution in Venice and Milan. He preserved Lombardy to Austria, routed the army of the Piedmontese at Custoza and Novara in 1849, concluded a treaty which assured Austrian supremacy in Italy for the time, and governed the Austrian possessions there until 1858 when he resigned. Consult: Troubetskoi, 'Campagnes du Comte Radetsky dans le Nord de l'Italie en 1848 et 1849' (1860); Kunz, 'Die Feldzüge des Feldmarschalls Radetsky in Oberitalien' (1890).

Rad'ford, **William**, American naval officer: b. Fincastle, Va., 1 March 1808; d. Washington, D. C., 8 Jan. 1890. He entered the navy in 1825, served in the war with Mexico, and performed gallant service at Mazatlan. When the Civil War broke out he was assigned to the Cumberland; was promoted captain in July 1862, and commodore in April 1863. During the assaults on Fort Fisher, in 1864-5, he commanded the New Ironsides and the ironclad portion of Porter's fleet. He was promoted to rear-admiral in July 1866, was in charge of the European squadron in 1869 and was afterward on duty in Washington until he was retired in March 1870.

Radhanpur, räd-han-poor', India, (1) chief town of a state in the Bombay presidency surrounded by a wall which encloses a fortified castle and the residence of the native prince. A fine sort of saltpeter is manufactured and there is some trade in cotton, wheat and grain. Pop. 14,722. (2) The state of Radhanpur in the northwest of Gujerat, covers an area of 1,150 square miles. Pop. 98,129.

Ra'dian. See MECHANICS.

Radiant Star, **Order of the**. See ORDERS (ROYAL) AND DECORATIONS.

Radia'ta, one of the great divisions of the animal kingdom in the classification of Cuvier, characterized by having the parts of the body arranged around a vertical axis like the spokes around the hub of a wheel. Later, it was shown by Leuckart that the group was unnatural, and it has been discarded for many years. Its chief numbers are now included in the *Calenterata* and *Echinodermata* (q.v.). As limited by Cuvier it also embraced some of the *Protozoa*, the *Polyzoa*, some parasitic worms, and a few other forms.

Radiation. By radiation is meant the propagation of energy in straight lines from a radiant point. This radiation is in the form of vibrations connected with an ether which fills

RADIATION

all space, both molecular and stellar. Such energy is best known as radiant heat, and when the vibrations are of sufficient rapidity to excite the nerves of vision, it is called light. Such a conception presupposes the origin of the radiations to be the oscillations of the ultimate particles of matter. The mode of propagation is a wave motion, to and fro, across the line of radiation. In sharp distinction from this was the material theory of heat, held by some physicists

FIG. 1.—The radiant energy from *a* traveling in straight lines is intercepted by the aluminum cross *b*, which casts its shadow at *d*.

previous to the investigations of Balfour Stewart, by which "caloric" or heat was regarded as "imponderable matter" stored up, or driven from bodies by chemical or mechanical means. Strange to say, the latest discoveries in radiation, point back to this long discarded theory.

Radiations of Heat and Light.—Physical science, at the opening of the 20th century, had established the mutual relationships of heat and light. (1) Both had been found to be propagated in straight lines, with a speed approximately of 186,000 miles per second. (2) The laws of reflection and refraction were the same in each. (3) The intensity of radiant heat, and that of light, varied inversely as the square of the distance. (4) Synchronism of vibration, interference of wave motion, and polarization were the same in each. (5) They were alike subject to selective absorption, and absorption was equivalent to radiation.

By means of the *spectrum*, the wave-lengths and frequency of vibration corresponding to different degrees of radiant heat, light, and actinic power had been ascertained. For instance, we know that, beginning at the lowest radiant heat measurable, we have in the neighborhood of 12,500,000,000 vibrations per second, and 944 millionths of an inch as the length of the wave. As the vibrations become more rapid and the length of the wave shorter, radiant heat becomes luminous and is known as light.

Vibrations and Wave-lengths.—With a vibration period of about 344,000,000,000 per second, and a wave-length of 32 millionths of an inch, particles of matter assume a dull red color. From this point on they pass successively through the colors of the spectrum—namely, red, orange, yellow, green, blue, indigo, and violet, until the eye, by reason of its physical limitations, ceases to take cognizance of them. At about 700,000,000,000 vibrations per second and a wave-length of 16 millionths of an inch, they are known as actinic or ultra-violet rays. The photographic plate responds to these rays up to 1,485,000,000,000 vibrations per second, with a wave-length of 7.95 millionths of an inch, and they will produce fluorescence up to a period of

1,621,000,000,000 vibrations, with a wave-length of 7.28 millionths of an inch. Scientific investigation is now largely confined to these *higher radiations*. As a starting point, we begin with investigations of Professor William Crookes, who discovered in 1879 that the highly attenuated matter in a vacuum tube, through which the discharge of an induction coil is passing, becomes luminous as the exhaustion of the tube increases. While Crookes' theory of a fourth state of matter, known as "radiant matter," has not been wholly approved or disapproved, it remains as the basis of modern discoveries in radiation. In all highly exhausted vacuum tubes, a small dark space surrounds the negative electrode during the electric discharge.

Radiations in Vacuum Tubes.—Crookes found that the dark space increases in length as exhaustion proceeds.

The explanation, according to Professor Crookes, is that the molecules of attenuated matter travel over comparatively long spaces before coming into contact with other molecules, which by their collision produce light.

The radiant energy within the tube travels in straight lines. Shadows are cast by intercepting objects, as in the case of light. (See Fig. 1.) Mechanical motion can be produced by directing the radiant energy against a light wheel. (See Fig. 2.) Crookes' radiometer, a familiar piece of apparatus seen in opticians' windows, operates on this principle and that of re-action. Significant discoveries in this connection followed: first, that the stream of radiant energy could be deflected by a magnet; second, that two streams of radiant energy re-

FIG. 2.—The stream of radiant matter from *a* strikes the upper vanes of the little paddle-wheel *b*, and causes it to roll along the rails. If the tube is inclined, the force is sufficient to drive the wheel up hill.

pelled each other, after the manner of matter similarly electrified; third, that the stream of radiant energy, when focused upon a metal, such as irido-platinum, heated it white hot. Glass also cracked and softened under its impact.

In 1894, Lenard, acting on a hint from Hertz, constructed a window of thin aluminum connected with the positive pole in Crookes' vacuum tube, and found that a faint bluish glow extended through the window into the air outside, and vanished at about two inches from the window. In this glow, uranium glass, calc spar, and a few other substances became phosphorescent. The radiations passed through screens of gold leaf, silver or aluminum easily. Electrically charged bodies were found to be discharged in the glow outside of the window and even beyond its visible limits.

Röntgen or "X-rays."—In 1895 Prof. Röntgen, of the University of Würzburg, discovered that a Crookes' tube covered with black card-

board emitted rays which penetrated the glass and cardboard. He immediately investigated their origin with a vacuum tube similar to Lenard's, but with a glass instead of an aluminum window, and found the source of these unknown rays in the window itself, where the impact of the radiation inside of the tube took place. He found that these unknown or "X-rays" were not the same as the radiation inside of the tube. The latter were deflected by a magnet, the "X-rays" were not.

The "X-rays" penetrated glass, tin, aluminum, or, generally speaking, metals of low atomic weight, while the radiant energy inside the tube possessed no such penetrating power. The "X-rays," however, will produce fluorescence—chemical action, and discharge electrified bodies—the same as ultra-violet rays. *They are not refracted, nor reflected, nor subject to diffraction, like light, and Prof. Alfred M. Mayer, of this country, has shown that they are incapable of polarization.* These latter facts regarding diffraction and polarization, as well as the non-interference of "X-rays," go to prove that they cannot be propagated according to the laws of wave motion, hence the theory of radiant energy assumed at the beginning of this article finds here an exception. In the case of the radiant energy within the vacuum tube, it seems evident that the phenomena are the result of streams of electrified particles of residual matter, shot off from the cathode in straight lines perpendicular to its surface. These flying particles falling upon anything in their path will give rise to "X-rays." The most important applications of the "X-rays" have been in the fields of anatomy, surgery, and diagnosis, where, owing to their ability to penetrate animal tissues, they have been extensively used to locate foreign bodies, and for the examination of dislocated bones and abnormal growths.

In 1896 M. Henri Becquerel discovered the presence of invisible radiations proceeding from the salts of uranium, and later from uranium itself—which radiations penetrated aluminum and produced shadow pictures somewhat after the manner of "X-rays." These radiations were proved to have their source within the substance of the uranium itself. This brings the subject of radiation down to the remarkable properties of radium, discovered by M. and Mme. Curie, of Paris, in 1898. See RADIUM.

J. R. PADDOCK.

Member of the American Association for the Advancement of Science.

Radiation of Heat. See HEAT.

Rad'ical, the name adopted by a large section of the Liberal party in Britain, which desires to have all abuses in the government completely rooted out, and a larger portion of the democratic spirit infused into the constitution. The immediate aim of Radicals at different times has necessarily varied considerably; and though the party is now identified almost exclusively with political reform, the Radicals of the past achieved their greatest success in compelling attention to important economic changes tending to improve the condition of the laboring population. The term is applied in general usage to persons of extreme views in connection with so-called political and social reforms.

Radical, or Radicle, in chemistry (and particularly in organic chemistry), a name given

to certain molecular groups whose constituent atoms possess such relations and affinities that the groups themselves persist and maintain their integrity, even when the compounds in which they occur undergo profound chemical change. The following example will illustrate the nature of a radical more clearly: Ordinary alcohol (ethyl alcohol), when free from water, has the chemical formula C_2H_5O . If this be saturated with hydrochloric acid gas in the presence of chloride of zinc, a compound having the formula C_2H_5Cl is formed; and by treating the alcohol with iodine under proper conditions, an analogous compound having the formula C_2H_5I is obtained. When this last substance is heated with water and metallic zinc, we obtain the hydrocarbon gas ethane, C_2H_6 . These reactions, and others of a similar nature, suggest that the molecular group C_2H_5 persists through all of these changes; and this hypothesis is found to be justified in every way. The group C_2H_5 is therefore a "radical," and to it the name "ethyl" has been given. The gas ethane, C_2H_6 , is the hydride of ethyl, according to this view, and its formula may be written $C_2H_5.H$. Similarly, C_2H_5Cl and C_2H_5I are known, respectively, as ethyl chloride and ethyl iodide. Ethyl alcohol, in the same way, is regarded as the hydrate of the radical ethyl, and its formula is written $C_2H_5.OH$. Ethyl is thus seen to be a monovalent radical with a high degree of stability, behaving, in its chemical relations, very much like the alkali metals, potassium and sodium. Many compounds are known in which two or more molecules of ethyl occur, with their combined valencies satisfying a single divalent atom or radical. Ordinary ether, for example, is the oxid of ethyl, its formula being $(C_2H_5)_2O$. The analogy of this substance with the oxid of potassium, K_2O , is complete.

If the persistence of a radical were absolute, so that we could never destroy the radical by any chemical or physical means, we obviously could not distinguish it from an element; and it is quite possible that some of the bodies that we now recognize as elements are merely radicals of extraordinary persistence, but which we may some day succeed in breaking up into their constituents. This is pure speculation, however, and until we know more about the ultimate constitution of matter, we are to regard a "radical" merely as a convenient conception, which enables us to simplify chemical formulæ, and to form a clear general view of the analogies and chemical relations that subsist among various chemical compounds. Radicals may be classed as "acid" or "basic," according as they have an acid or a basic character. Thus the radical SO_4 , which occurs in sulphuric acid and in the sulphates, and which is called "sulphion," is an acid radical, while ethyl, C_2H_5 , is basic.

Among the simpler inorganic radicals that are of frequent occurrence, the following are monovalent: Hydroxyl (OH), the "nitro" group (NO_2), the "nitroso" group (NO), the "amido" group (NH_2), and cyanogen (CN). The following are divalent: Sulphion (SO_4), sulphuryl (SO_2), the "imido" group (NH), and the "thionyl" group (SO). In organic chemistry many radicals are recognized. The commoner basic radicals of the fatty series may be re-

garded as derived from the saturated hydrocarbons (or paraffins) by the removal of one or more atoms of hydrogen. Thus we have the following series, which are derived in the manner described, the radicals in each column being obtained from the paraffin at the head of that column by the removal of hydrogen atoms:

| | | | | |
|-----------------|-------------------------------|-------------------------------|--------------------------------|--------------------------------|
| CH ₄ | C ₂ H ₆ | C ₃ H ₈ | C ₄ H ₁₀ | C ₅ H ₁₂ |
| Methane | Ethane | Propane | Butane | Pentane |
| CH ₃ | C ₂ H ₅ | C ₃ H ₇ | C ₄ H ₉ | C ₅ H ₁₁ |
| Methyl | Ethyl | Propyl | Butyl | Pentyl |
| CH ₂ | C ₂ H ₄ | C ₃ H ₆ | C ₄ H ₈ | C ₅ H ₁₀ |
| Methylene | Ethylene | Propylene | Butylene | Pentylene |
| CH | C ₂ H ₃ | C ₃ H ₅ | C ₄ H ₇ | C ₅ H ₉ |
| Methenyl | Ethenyl | Propenyl | Butenyl | Pentenyl |
| C | C ₂ H ₂ | C ₃ H ₄ | C ₄ H ₆ | C ₅ H ₈ |
| (Carbon) | Ethine | Propine | Butine | Pentine |

The names here assigned to the radicals are due to Hofmann, and the system in accordance with which they are formed will be sufficiently evident, without further explanation. Hofmann's names are now commonly adopted, but some of the foregoing radicals are still known by other names also. Thus Hofmann's "ethenyl" is often called "vinyl"; and, similarly, his "propenyl," "butenyl," "ethine," "propine," and "butine" are respectively known as "glyceryl," "crotyl," "acetylene," "allylene," and "crotonylene."

The radicals tabulated above, and which are of constant occurrence in organic chemistry, contain only hydrogen and oxygen. Many organic radicals are known, however, which contain other elements also. The first oxygen-bearing group to be recognized as a radical was "benzoyl," C₆H₅CO, which occurs in benzoic acid, and in many other compounds that are related to the oil of bitter almonds. This radical was recognized by Liebig and Wöhler, in 1832. Many such radicals are now recognized, especially in the organic acids and their derivatives. As an example, "acetyl" may be cited. This has the composition C₂H₃O, and acetic acid, C₂H₃O.OH, is its hydrate.

Many of the radicals are not capable of independent existence, and hence cannot be isolated. Others may be obtained in the free state, or in the form of a compound in which two similar radical groups are united to each other. When methyl iodide is heated with metallic zinc, the iodine is taken up by the zinc, and the methyl radical, CH₃, is liberated. It is not obtained in the form of methyl, however, for at the moment of its liberation two of the radicals combine to form a molecule of ethane, C₂H₆. Ethane, therefore, may be regarded as "di-methyl," having the formula CH₃—CH₃, or as "ethyl hydride," having the formula C₂H₅H. It is convenient to regard it from one of these points of view for some purposes, and from the other for other purposes. A radical of the series tabulated above can exist in the free state, save for a slight change in its internal linkage, provided its valency is an even number, and the free bonds belong to adjacent carbon atoms. Ethylene, for example, has the formula C₂H₄. When it exists as a radical, in combination with other atoms, it is divalent, and has the structure

—CH₂
|
—CH₂ ; the two carbon atoms being connected by one internal bond, while each carbon atom also has one bond which is satisfied by the ex-

ternal atoms with which the radical is combined. When the ethylene exists as a free hydrocarbon, the two free bonds shown in the foregoing rational formula satisfy each other, and the constitution of free ethylene therefore:

The idea of a compound radical is due to Lavoisier; and the conception, although its validity was earnestly disputed for some years, has been of great importance in the development of chemistry. The definition of a radical, as given by Liebig in 1838 in his discussion of cyanogen, holds good at the present day. He said: "We call cyanogen a radical because (1) it is the invariable constituent in a series of compounds; (2) because it can be replaced in these compounds by other simple bodies; (3) because in its compounds with a simple body the latter can be replaced by equivalents of other simple bodies." At least two of these three characteristics must be fulfilled by a group of atoms, before that group can be regarded as a "radical."

Editorial Staff, 'Encyclopedia Americana.'

Radiguet, Maximilien René, French explorer; b. Landerneau, Finisterre, 17 Feb. 1816; d. 1892. He was educated in the School of Fine Arts at Paris, and in 1838 became secretary to Admiral Charles Baudin and Count de Las Casas, on a mission that had been sent to Haiti to negotiate with the government of that country for the payment of an indemnity to the descendants of the French citizens that had been murdered during the troubles of 1798-1803. His influence was of great value in bringing the negotiations to a speedy conclusion, several times preventing the impatient admiral from bombarding Cape Haytien. He was afterward secretary to Admiral Du Petit-Thouars, 1841-5, and traveled through South America and the Marquesas Islands, and afterward devoted himself to literary labors. Among other works he has published 'Souvenirs de l'Amérique Espagnole: Chile, Pérou, Brésil' (1856; revised ed. 1874).

Radioactivity. Although only nine years have elapsed since Becquerel (1896) discovered that uranium possessed the property of spontaneously and continuously emitting penetrating rays, capable of passing through bodies opaque to ordinary light, our knowledge of the subject of radioactivity has increased with great rapidity and a very large mass of experimental facts has now been accumulated. Only a very brief account of the remarkable properties possessed by the radioactive bodies is possible in this short article.

Shortly after the discovery of this property in uranium, Mme. Curie and Schmidt independently found that the heavy element thorium, which is used in the manufacture of Welsbach mantles, was also radioactive and to about the same degree as uranium. The latter substance is commercially obtained from the mineral pitchblende and in an examination of the radioactive properties of this mineral, Mme. Curie was led to the conclusion that other and more

RADIOACTIVITY

radioactive substances must be present in it. By an admirable piece of chemical research, Mme. and P. Curie succeeded in separating from it two new very active substances which were called radium and polonium. The substance radium was well named as, in the pure state, it gives out radiations about two million times as intense as uranium. Polonium has not yet been chemically isolated. It differs from radium in losing its activity with the time. Several years after separation, the activity has diminished gradually to a small fraction of its original value.

Another substance called radio-tellurium was separated from pitchblende by Marckwald. It has radioactive properties similar to polonium, and probably contains the same radioactive constituent. In addition to these bodies, Debierne and Giesel independently discovered another very active substance called actinium, while Hofmann found that lead separated from pitchblende was very active and called the radioactive substance present in it "radio-lead." With the exception of radium, none of these bodies have been chemically isolated. Actinium (or emanium, as it is termed by Giesel,) will probably prove to be an element of activity comparable with that of radium.

The radiations from these substances are invisible to the eye, but possess the properties of acting on a photographic plate and discharging an electrified body. The rays from a very active substance like radium cause many phosphorescent substances to become luminous. An ordinary X-ray screen, crystalline zinc sulphide and the minerals willemite and kunzite glow brightly when exposed to radium rays. A photographic plate is rapidly affected by bringing near a few milligrams of radium bromide, and an electroscope quickly loses its charge.

The radiations from the active bodies have been shown to consist of three distinct kinds, known as α , β , and γ rays. Unlike ordinary light-waves, the α and β rays consist of a flight of charged particles projected with enormous velocity. They differ from ordinary light, inasmuch as pencil of these rays is deflected by a magnetic and electric field. These properties of the radiations have allowed us to determine the size of the particle and its velocity of projection. Rutherford found that the α rays consisted of atoms of matter carrying a positive charge and moving with a velocity of about 20,000 miles a second. The α rays are readily stopped by matter, being absorbed by a few centimetres of air and by a sheet of ordinary note paper. The β particles, on the other hand, are far more penetrating and pass through several millimetres of aluminum or iron. The β particles differ from the α particles in carrying a negative charge and in their much greater velocity of projection. Some of them move with a velocity of over 170,000 miles per second—a speed very nearly equal to that of light. The β particle has been found by Becquerel and Kaufmann to be identical with the cathode particle produced by a discharge in a vacuum tube. It has the smallest size of any body known to science, for its mass is only about 1-1000 of that of the atom of hydrogen. The relative sizes and velocities of the α and β particles are diagrammatically shown in Fig. 1. The relative energies of motion of the particles are also shown.

The γ rays are of an extraordinarily penetrating character, readily passing through several inches of iron or lead and several feet of water. They are not deflected by a magnetic or electric field and are believed to be a type

| | MASS | VELOCITY | ENERGY |
|----------|------|----------|--------|
| α | ○ | — | ⊗ |
| β | • | —— | • |

FIG. 1.

of very penetrating X-rays. The latter are believed to consist of pulses in the ether, akin in some respects to the very short waves of ultra-violet light.

If a magnetic field is applied to a pencil of rays from radium, the rays are sorted out into the three kinds. This is shown in Fig. 2, where the magnetic field is applied at right angles to the plane of the paper. The α particles are bent to the left, the β to the right, while the γ rays proceed in a straight line without deviation. Compared with the β rays, the amount of bending of the α rays is much exaggerated in the figure, for a very strong magnetic field is required to appreciably deflect the latter. The β rays consist of particles projected with different velocities, so that some are more easily bent by a magnetic field than others. This is shown in the figure.

FIG. 2.

The expulsion of α and β particles from the atoms of the radioactive bodies appears to result from an explosion in some of the atoms of these substances. About two hundred thousand million of these α particles are expelled from one gram of radium bromide every second; and yet the number of atoms in a gram of radium is so enormous that this rate of expulsion can continue for several years without any

RADIOACTIVITY

sensible alteration or diminution of the quantity of radium.

The most important property of the α , β , and γ rays is their power of discharging an electrified body, and this property has been utilized as a means of quantitative measurements of

FIG. 3.

the radiations. The ordinary gold leaf electroscope, such as is shown in Fig. 3, can be used to measure radiations of extremely small intensity. A simple gold leaf is attached to a metal rod passing through an insulating cork of sulphur or ebonite. On giving a charge to this rod, the gold leaf diverges and, under ordinary conditions, the gold leaf collapses very slowly. If, however, a radioactive substance is brought near it, the charge on the system is dissipated and the gold leaf rapidly collapses.

The radiations produce a large number of positively and negatively electrified particles or ions, as they are called, from the neutral gas. If the electroscope is charged positively, for example, the negative ions are drawn into it and dissipate its charge. Under suitable conditions, the rate of movement of the gold leaf is a measure of the intensity of the radiations. A modified form of gold leaf electroscope is capable of detecting the presence of an extraordinarily small quantity of radioactive matter. One millionth of a gram of radium bromide causes the gold leaf to collapse in a few seconds, and, with care, the effect of one million millionth of a gram can be accurately determined. As a means of detection of radioactive matter in small quantity, the electroscope far transcends in delicacy even the spectroscope. The ordinary quadrant electrometer is also a very convenient instrument for measuring the small ionization produced by the radiations in the air or other gas through which they pass.

In addition to their power of giving out the three kinds of rays, radium, thorium, and actinium also possess another very remarkable property. Each of these substances continuously gives off into the air a minute quantity of gas, which is itself radioactive. This "emanation," first discovered by Rutherford in thorium,

gradually diffuses from the radioactive body into the surrounding gas and can be carried away with a current of air. The "emanations," however, only keep their power of radiating for a short time.

The activity of the emanation decreases in a geometrical progression with the time; the emanation from thorium loses half of its activity in one minute; from radium in four days; and from actinium in four seconds.

The amount of emanation obtained from these substances is a maximum when in solution; in a solid state only a fraction of the emanation produced in the substance is able to escape from it.

These emanations have been found to possess all the properties of radioactive gases mixed in minute quantity with the air. The emanations of thorium and radium behave like heavy gases and are chemically inert like the recently discovered members of the argon-helium family. The emanations can be removed from the air by the action of extreme cold. The emanation of thorium condenses at -120°C ., and that from radium at -150°C . This property of condensation of the emanation from a very active substance like radium can readily be followed by the eye. The emanation released from radium is stored with air in a small reservoir (Fig. 4). It is slowly passed through a U tube of glass, filled with fragments of the phosphorescent mineral willemite. The tube is immersed in a vessel filled with liquid air. The emanation condenses in the tube immediately below the level of the liquid air, and the radiations from the condensed emanation cause the willemite to become luminous. On removal of the tube and closing the ends, the emanation, after some time, is again volatilized and distributes itself throughout the tube, causing a uniform luminosity

FIG. 4.

throughout it. With a large quantity of radium emanation, such an experiment is extremely striking.

Ramsay and Soddy have succeeded in isolating the emanation of radium, and found that the maximum volume to be obtained from one gram of that substance was only one cubic millimetre at standard pressure and temperature. This gas is brilliantly luminous and rapidly blackens the tube containing it. The emanation has a definite spectrum of bright lines, similar in general character to that observed for the inert gases argon or helium.

Curie and Laborde first observed the striking

RADIUM AND OTHER RADIOACTIVE SUBSTANCES.

RADIOACTIVITY

fact that radium kept itself continuously at a temperature several degrees higher than the surrounding air. The radium is continuously emitting heat at the rate of 100 gram calories per hour; that is, it would heat its own weight of water through 100° C. in one hour. Rutherford and Barnes showed that the greater part of the heating effect of radium was not due directly to the radium itself, but to the emanation continuously produced from it. This emanation was separated from the radium, and condensed in a small glass tube immersed in liquid air. The heating effect of the minute quantity of emanation thus obtained was found to be three quarters of that originally possessed by the radium. Compared with its weight, the radium emanation emits a quantity of energy more than a million times greater than that released in the most violent chemical reaction. The heating effect of the emanation is not, however, permanent, but dies away with the time at the same rate as it loses its activity; that is, it falls to half value in about four days.

If a cubic centimetre of the emanation were collected in a glass tube, it would probably give off sufficient heat to melt down the walls of the tube. It can readily be deduced that one pound weight of the emanation, after its separation from radium, would emit energy at the rate of 10,000 horse-power and, during the time that its activity lasts, would emit an amount of energy corresponding to 60,000 horse-power days. The heating effects of radium have been found to be directly due to the expulsion of α particles from its mass. Each of these particles is projected with such a great velocity that it has considerable energy of motion, which is transformed into heat when it strikes a body. These α particles are easily stopped by matter and, in a mass of radium, most of the α particles projected throughout its volume are not able to escape, but are stopped by the radium itself. Radium is thus heated by the unceasing and vigorous self-bombardment by the α particles shot out from its own mass. The heating effect of the emanation, in a similar way, is due to the energy of motion possessed by the α particles expelled from it.

The emanations all show another very striking property. If the emanation is drawn through a tube, the surface of the tube becomes coated with an invisible active deposit. This deposit can be dissolved in acids, and after evaporation of the solvent, remains behind on the dish. After removal of the emanation, the deposit gradually loses its activity but at a different rate from the emanation itself. This "excited" or "induced" activity, as it is termed, is due to radioactive matter which arises from the decomposition of the emanation. The excited activity of thorium falls to half value in 11 hours, that of radium in about 30 minutes, and that of actinium in 36 minutes.

Considerable light was thrown on radioactive phenomena by some experiments of Rutherford and Soddy that will now be considered. It was found that an intensely active substance called thorium X could be separated by a single chemical process from thorium. If some thorium nitrate is dissolved in water and ammonia added, the thorium is precipitated. If the ammonia solution is then evaporated and ignited, a very active residue is obtained, sev-

eral thousand times more active, weight for weight, than thorium itself. The thorium itself is at the same time deprived of more than half of its original activity. A very interesting result is then observed. The activity of this residue thorium X is found not to be permanent but to decay according to a geometrical progression with the time, falling to half value in four days. At the end of a month, the activity is less than 1 per cent of the initial value. At the same time, the precipitated thorium regains its lost activity, such that the sum of the activity of the thorium and thorium X together is always the same, and equal to that of the original thorium before chemical treatment. At the end of a month's interval, the thorium has nearly recovered its old value, and a new quantity of thorium X can then be obtained by the same chemical operation. This process can be continued indefinitely provided sufficient interval is allowed to elapse between each precipitation for the thorium to regain its activity. These results are very simply and fully explained on the following hypothesis. A small fraction of the thorium atoms every second becomes unstable and breaks up with explosive violence, an α particle being projected during the process. After the expulsion of an α particle, the residue of the thorium atom is lighter than before and becomes the atom of the new substance, thorium X. This substance is again unstable and breaks up with the expulsion of α particles, half of the matter breaking up in four days. In ordinary thorium, there are thus two opposing processes at work. The substance thorium X is produced at a constant rate by the disintegration of some of the thorium atoms, and at the same time this thorium X breaks up and changes into another substance. A steady state will obviously be reached when the number of atoms of thorium X, which are produced per second, is equal to the number of atoms of thorium X which break up per second. The constant radioactivity of thorium may thus be likened to the constant population of a country, where the number of births is equal to the number of deaths.

It has been found experimentally that the property possessed by thorium of giving off an emanation belongs not directly to the thorium but to its product, thorium X. The amount of the emanation is always proportional to the amount of thorium X present, and thorium freed from thorium X does not emit any emanation. This shows that thorium X is the parent of the emanation. According to the disintegration theory, advanced by Rutherford and Soddy, the atom of the emanation arises as a result of the expulsion of a particle from the atom of thorium X. In a similar way it has been shown that the emanation is transformed into the active deposit which has been found to consist of two distinct substances called thorium A and thorium B. The former does not give out rays at all, and is half transformed in 11 hours. It changes into the substance thorium B, which gives out α , β , and γ rays, and is half transformed in 55 minutes. The active deposit usually consists of thorium A and B together. These two constituents can be separated from one another by electrolysis, or the same may be done by utilizing the differences in their volatility when subjected to heat.

RADIOACTIVITY

These "rayless" products, of which there are now several examples, are of great interest. These substances are transformed without the appearance of any noticeable radiation. This may be the result either of a rearrangement of the parts of an atom, or may be due to the fact that the α particle is not released with sufficient velocity to produce ions in the gas. It is interesting to note that the chemical and physical properties of a rayless product can be determined by observing its effect on the succeeding product which emits rays. Thus we can learn the properties of a substance which we are unable to directly observe either by its weight or its radiations.

and the radiations which accompany its transformation are also added.

It will be seen that seven distinct transformation products have been found in radium. The active deposit of rapid change arising from the emanation consists of three substances, called radium A, B, and C, which are half transformed in 3, 21, and 28 minutes, respectively. After these products have undergone transformation, a residue of very slight activity remains. The properties of this residue have been analyzed by Rutherford, who has shown that it breaks up through three successive stages, called radium D, E and F. The substance radium D does not give out rays itself, and is transformed very

The process of analysis which has been applied to thorium has been applied with equal success to uranium, radium, and actinium. Sir William Crookes found that uranium has a product called uranium X, which is half transformed in 22 days and gives out only β and γ rays. The product actinium X was recently discovered by Godlewski. The radioactive properties of actinium are very similar, as will be seen from their stages of transformation given later. It is impossible in this short article to discuss in detail the experiments by which the presence and properties of these series of products, resulting from the transformation of the radio-elements, have been determined. The conclusions arrived at are shown diagrammatically in Fig. 5. The time for each product to be half transformed is placed below the product,

slowly—about half value in 40 years. The examination of this residue has brought to light the very important fact that radio-tellurium, and probably also polonium, are products of the disintegration of radium. The product radium F is identical with the radio-tellurium of Marckwald, for their chemical and physical properties are the same, and both lose their activity at the same rate. It has also been shown that radium D is probably the primary substance, which causes the activity observed in the radio-lead of Hofmann. The active substances present in polonium, radio-tellurium, and radio-lead are thus proved to be members of the radium family.

The products obtained from the radio-elements all possess some distinctive physical and chemical properties, which distinguish them not only from other products but also from the

RADIOACTIVITY

parent element. For example, radium—a solid substance with chemical properties closely allied to barium—is transformed into a gaseous substance, the radium emanation. The emanation in turn is transformed into a solid. Each of these products must be considered a distinct chemical substance. They differ from the ordinary chemical elements in the fact that they are unstable and undergo transformation into other or new kinds of matter. On account of their very limited life, these products exist in very minute quantity, and it is only in the case of a comparatively slowly changing product like the radium emanation that a sufficient amount can be obtained to measure. There is no doubt, however, that both radium D and F will ultimately be obtained in sufficient quantity to obtain their spectrum and chemical constants.

In the radio-elements, we are witnessing the transformation of matter through a series of successive stages. The products represent the halting places where the matter is able to exist a short time before it breaks down into new forms. This process of transformation is spontaneous and, as far as observation has at present gone, cannot be hastened or retarded by any physical or chemical agencies.

Since the radio-elements are steadily being transformed, the original matter must slowly disappear and be changed into other kinds. It can be calculated with some confidence that radium will be half transformed in about 1,000 years. A feebly active substance like uranium will probably take one thousand million years to be half transformed. The radio-elements apparently only differ from their products in their length of life; that is, in the stability of the atoms composing them.

A mass of radium left by itself would, in the course of 20,000 years, be almost completely transformed. Since the age of the minerals in which radium is found is known to be much older than this, it is necessary to suppose that radium is constantly produced from some other substance. The most likely parent of radium is the heavy element uranium, with which it is always found associated. Such a view has been strongly confirmed by recent investigations of Boltwood, Strutt, and McCoy. Boltwood has found that the amount of radium in different radioactive minerals, obtained from different parts of the world, is always proportional to their content of uranium. Such a relation indicates that radium is derived from uranium. If this is the case, a quantity of uranium, initially freed from radium, should in the course of time produce some radium. Such a growth of radium from uranium has actually been recorded in some recent experiments by Soddy and Whetham. The rate of production observed is, however, much slower than is to be expected if uranium passes directly into radium. The evidence is thus very strong that one element uranium produces another distinct element radium, which is quite distinct in chemical and physical properties from its parent.

In Fig. 5, we have given the series of bodies produced by the transformation of the radio-elements. But this process of transformation must ultimately come to an end and we should thus expect that the final product should be inactive, and probably consist of a known element or elements. Now the substance lead is always

found in small quantity in minerals, and it is possible that this substance may prove to be the final or end product of radium.

The radioactive minerals must be considered as nature's laboratory in which all the products of transformation of the radioactive substances will be found. Rutherford and Soddy early suggested that the rare gas helium, which is always found associated with the radioactive minerals was a transformation product of the radio-elements. This prediction was verified by some very striking experiments made by Ramsay and Soddy. They removed the emanation from a quantity of radium and collected it in a tube. A discharge was passed through this tube and the light examined by a spectroscope. After standing several hours the spectrum of helium was observed, showing that this gas had been produced during the transformation of the emanation. Here again we have an example of the production of one element helium from another.

It seems likely that the α particles which are projected from the radio-elements are in reality helium atoms, but the amount of helium produced from radium is so small and difficult to measure that it is not easy to definitely settle the question of the position which helium occupies in the scheme of transformation outlined in Fig. 5.

The helium found in radioactive minerals is thus a decomposition of radium and probably also of the other radioactive substances present in it. It seems likely that we shall be able to form a rough estimate of the age of the radioactive minerals by measuring the amount of helium found in them, since for a given amount of radioactive matter present, the amount of helium will be greater, the longer the mineral has been formed.

Although radium is found in the greatest quantity in the mineral pitchblende, it is also found distributed in minute quantity over the whole surface of the earth. This has been clearly brought out by the long series of investigations made by Elster and Geitel of the radioactivity of different soils and of the atmosphere. J. J. Thomson, Himstedt, Strutt and many others have found that the radium emanation is present in springs and in well water. Bumstead and Wheeler found that the air and surface waters of New Haven, Connecticut, was impregnated with the radium emanation. Strutt and Allan have observed that the famous Bath springs contain a considerable amount of radium emanation, and the former has also shown that the water contains a minute amount of radium in solution. A similar result has been noted for the waters at Baden and elsewhere. It has been suggested that the curative properties of these hot-water springs may possibly be due to the presence of radium or the radium emanation. This has, however, by no means been established.

The atmosphere is found to always contain a small quantity of the radium emanation. This does not come from the atmosphere itself but diffuses up from the soil or is carried up by spring water. A large amount of investigation has been carried out to determine the amount of emanation present in the atmosphere at different localities and under varying atmospheric conditions.

It has been suggested that the internal heat of the earth may be, in part at least, kept up by the heat liberated by the radium and other radioactive matter present in it. Observations, that have so far been made, seem to show that the amount of radium in the surface crust of the earth is sufficient to supply as much heat to the earth as is lost by conduction to the surface from the hot interior of the earth. It is only necessary that radium should exist in the earth to the extent of four parts in one hundred million million to account for the maintenance of the internal heat of the earth. The amount of radium or equivalent amount of other radioactive matter present in the earth cannot be greater than 270,000,000 tons or otherwise the earth would be growing hotter.

It is not possible to discuss here the physiological actions that are produced by radium rays. A large number of experiments have already been made and the literature of this branch of the subject is already extensive and is very rapidly growing. E. RUTHERFORD.

Prof. of Physics, McGill University, Montreal.

Radiometer, an instrument used to measure mechanical effect of radiant energy. It consists of four crossed arms of very fine glass, supported in the centre by a needle-point having at the extreme end thin disks of pith, blackened on one side. The instrument is placed in a glass vessel exhausted of air, and when exposed to rays of light or heat the wheel moves more or less rapidly in proportion to the strength or weakness of the rays.

Radiophone, an instrument that transmits or produces sound by means of radiant energy, particularly a device similar to the photophone, whose receiver is a block of vulcanite, with no telephone, the vibratory contraction and expansion being produced by the heat of the beam while vibrating, which is accompanied by an audible sound.

Radiotherapy is a term broadly used to designate the uses of the X-rays in the treatment of disease.

Scarcely had the diagnostic wonders of the X-rays been brought before the world by Professor Röntgen than X-ray operators and clinicians became cognizant of the deleterious effects which sometimes followed prolonged or frequent exposures for diagnostic purposes.

Partial or complete loss of hair over the part rayed; atrophy of the nails, and inflammations and destructive disturbances in the skin followed, varying from a simple redness, or a transient dermatitis to extensive ulcerations which healed most unkindly if at all.

It was only a step farther to adapt this little known and powerful agency to a beneficent purpose.

Within two years after Röntgen published his original paper, Freund* detailed the results of two experiments in the treatment of hypertrichosis (superfluous hair on face), in which a disappearance of the hairs followed frequent and prolonged exposures. In one of the cases reported by Freund after a number of exposures which aggregated over 40 hours, a violent and severe inflammation of the skin was set up which finally resulted in ulceration and necrosis.

The caustic action of the X-rays as seen in this case suggested to Schiff of Vienna the possibility of its use in the treatment of lupus vulgaris.

Independent of the work of Schiff and deducing his reasons from an entirely different hypothesis, Dr. Philip Jones of San Francisco as a result of the studies of the action of X-rays on a photographic plate, claimed and proved that the X-rays would cure lupus.

Dr. Jones' theory was that: the action of the X-rays on a photographic plate was a decomposing one, hence the X-rays ought to break down the highly organized lupus tissue. His results proved the soundness of his theory.

The fact that hypertrichosis and lupus, two of the most intractable diseases that bothered the dermatologist, could be successfully combated by the X-rays, naturally gave a great impetus to radiotherapy.

The already large number of X-ray investigators working along diagnostic lines quickly turned their attention to the therapeutic action of the rays and the literature soon became extensive.

Many intractable skin diseases readily cleared up under the action of the rays. Closely following the successful results in lupus, epitheliomas or skin cancers, rodent ulcers, and new growths of that type showed the favorable results of this treatment.

The breaking down of these highly developed tissues naturally led to the treatment of ulcerating breast cancers, scirrhus or hard breast cancers, and finally the attempt to eradicate internal cancers, with the results at present still in doubt. Accompanying many of the conditions treated was pain.

It soon became recognized that after a certain number of treatments the pain was oftentimes materially decreased, and in some instances entirely disappeared, hence it naturally followed that the X-rays were used in many painful affections of the nerves, neuralgias, sciaticas and for the relief of pain in inoperable cancers.

From an observation of the action of the X-rays on cancerous glands, treatment of enlarged glands from other causes was instituted and soon favorable results were recorded in cases of tubercular glands, Hodgkins disease, spleno-medullary leukemia and many allied conditions. Tuberculosis in all its varied manifestations soon was given a thorough trial. The results were eminently satisfactory in some forms, but disappointing in consumption and diseases of the bones and joints.

Having attempted to trace the beginnings of radiotherapy and the investigations which led up to it: How the action of the rays in certain conditions gradually and methodically paved the way for its employment in others, it might be advantageous here to take up the means and methods whereby these results are obtained and the protection and safeguards necessary for their successful attainment.

Apparatus.—Any form of apparatus that can successfully develop Röntgen rays may be used in radiotherapy.

The three principal styles in use are (1) the induction coil, (2) the static machine, (3) the high frequency or Tesla apparatus. The last named is so seldom used that a discussion of its merits may be dismissed.

*Wiener Med. Woch. 1897.

1. Radiograph of the human hand (dead) made by radium.
2. Radiograph of the human hand (living) made by "X" rays.

RADIOTHERAPY

Some operators prefer the static machine to the coil and claim better results for the former, while workers with coils claim the opposite.

Most men who have an opportunity to employ both recognize no great difference. It is probably true that more inefficient work is done with static machines than with coils because many static machines employed fail to develop sufficiently heavy electrical discharges to satisfactorily illumine a practical tube while capable of doing satisfactory static work. Most coils employed are sufficiently large to overcome this difficulty.

A great many factors are present in determining the intensity and quality of the rays. The amperage must be low, between one and four amperes, but the voltage may range from 12 to 110 volts.

Tubes.—In radiotherapy the tube is one of the most essential elements that control results. The character of the tube will largely be governed by the results sought. Tubes invaluable for the treatment of certain conditions are useless for the treatment of others. For hypertrichosis a rather low tube with short penetration accomplishes the most successful results, because here we seek an absorption of the rays around the hair follicles. The same is true of any thin-surfaced skin disease. But in treating morbid conditions of the deeper parts a tube is needed with a higher vacuum, because here we aim to have the rays penetrate the skin unabsorbed and act on the affected parts underneath.

There are in use three principal styles: (1) The unregulated X-ray vacuum tube. (2) The tube with a regulated attachment, whereby the vacuum of the tube may be lowered when it becomes too high, by heating a metallic needle which projects from the tube. This needle upon being heated liberates gases in the tube which lower the vacuum. This style of tube has a much longer life than a tube of the preceding style, and is quite satisfactory for radiotherapeutic work. (3) The highest type of tube is the one with the self-adjusting vacuum; a tube under absolute control even when excited. This tube does excellent work, is essential for the finer grades of radiographic work, but it is costly, punctures more readily and its advantages in radiotherapy do not compensate for its added cost. There are various special tubes manufactured for the treatment of special parts, as the larynx, vagina, rectum. These have their advantages.

Distance.—The distance of the tube or the cathode from the part to be treated varies with the conditions to be treated and the character of the tube. In those diseases where it is desirable to set up an action in the skin quickly, the tubes may be placed so that the outside of the glass is within two or three inches of the part treated. When treatment is to be continued for a long time and an inflammatory action is guarded against, the tube may be removed 12 to 15 inches.

Protection.—Most operators at the present time use a metallic protection to the normal parts, either lead or tinfoil. Grounded aluminum shields have been used, but they are unnecessary. Liquid paraffine and substances with an ointment base have been tried, but they do not offer sufficient protection. Many men in treating recurrent cancers place the tube at some

distance from the patient, and use no protection. This has the advantage that widely infected areas are acted upon.

Exposures.—Exposures may be made every day, every other day, twice a week or by Kienböcks* method, which seeks to accomplish a therapeutic effect oftentimes with a single exposure from a heavy coil and an intense light. When given daily, treatments are generally short, five minutes. The generally accepted plan is to expose the patient three times a week from 8 to 15 minutes, varying with the condition to be treated. It is practically accepted that there is an idiosyncrasy among some persons to the influence of the rays, and the most cautious operators give a preliminary exposure to determine this susceptibility to X-ray action.

Dermatitis.—There is no more debatable question in the whole realm of X-ray work than the question of the X-ray burn. A discussion of the pathology of X-ray dermatitis is foreign to the subject at hand; if interested the reader is referred to the works of Williams, Pusey and Caldwell, and the experiments of Prof. Elihu Thomson and others. It is sufficient to know that in the treatment of many diseased conditions it is wholly unnecessary to set up a dermatitis. Lupus, syphilis, cutaneous cancer and the malignant ulcerations can be entirely healed without producing inflammation of the skin beyond a slight redness or a tan. That this is so entirely disposes of the theory that the action of the X-rays in curing disease is caustic or escharotic. While it is wholly unnecessary to produce a burn to cure, in many cases haste is so imperative that in order to quickly get a patient under the influence of the rays all caution must be set aside.

Indications for Radiotherapy.—The following classification is given by Pusey†: (1) The effect in causing atrophy of the appendages of the skin; (2) their destructive action upon organisms in living tissues; (3) their stimulative action upon the metabolism of tissues; (4) their power of destroying certain pathological tissues; (5) their anodyne effect.

Under one class may be included the action of the rays in removal of superfluous hair or in alleviating conditions due to parasitic affections of the hair or its follicles: hypertrichosis, syphilis, favus, tinea-tonsurans, tinea-barbæ. In this class of cases the results of treatment are completely curative. The removal of superfluous hair from ladies' faces (complete patches) during one course of treatment is so far superior to the long, tedious, painful method of destroying each individual hair follicle by the electric needle that it requires no comment. Sometimes, if the reaction is not sufficiently severe, the hair may recur in a lessened amount, but a second series of treatments usually will produce a permanent cure.

Another group of cases would include the inflammatory diseases of the skin: Lupus-erythematosus, acne, chronic indurated eczema, lichen planus, psoriasis and affections of that class. In this group are many diseases, the medical treatment of which is entirely satisfactory. The most intractable and unsatisfactory condition in this class is probably lupus erythe-

*Interstate Med. Journal, 1902, ix., pp. 1-60.

†Pusey & Caldwell, "The Röntgen Rays in Diagnosis and Therapeutics."

matosis. This disease is characterized by its tendency to remissions, and, unfortunately, it retains its characteristics when treated by the X-rays. There have been many cases of lasting cures, but that there are many other cases which recur after recovery seems probable, and some that radiotherapy does not beneficially affect.

There are many diseases which are caused by the action of bacteria in the skin, and subcutaneous tissues, in which there are obtained most brilliant, positive and curative results by the action of the Röntgen rays. Although the evidence is conflicting, yet it is generally accepted that the X-rays exert little or no bactericidal power on germs in culture media, but it is just as positive that the X-rays most powerfully affect diseased tissue containing germs. Whether this action is due to a stimulating effect upon the tissues themselves, making them a less receptive host for the bacteria, or whether it acts directly and destructively on bacteria and their products in living tissue, is still *sub-judice*.

The most remarkable results obtained in this class of cases are in lupus vulgaris. Before the epoch-making work of Finsen, of Copenhagen, the treatment of lupus vulgaris was most discouraging. The most persistent and continuous treatment, from cauterizations to extensive plastic work of the surgeon, could only for a time arrest the slow but steady destructive ulcerations. Some few cases were cured, but the percentage of recoveries was small, until Finsen showed his lasting cures by the ultra-violet rays. The treatment of Finsen leaves little to be improved upon so far as results go. But the treatment is unsatisfactory because of the expensive equipment, duration of each treatment, pain during treatment, and time required to effect a cure: it sometimes taking a year of almost daily treatment to eradicate a patch of an inch.

The results of X-ray therapy seem equally as good as Finsen's, while 15-minute treatments, 6 to 20 times, and given every other day, accomplish the same results. In treating lupus by means of the X-rays, the most lasting and successful results are obtained in the deeply ulcerated cases by establishing a severe dermatitis. While in the surface inflammations we may obtain a cure without producing the slightest effect on the surrounding normal skin.

At the present the X-rays seem to offer hope of a permanent cure in many of the non-malignant glandular enlargements, where it acts by breaking down tissues of low vitality without injuring the healthy connective tissues. Tubercular glands in the early stages show a fair percentage of cures. Hodgkins disease—an almost universally fatal condition—has shown many authentic cures, and recently Senn and others report cures of spleno-medullary leukemia. Care must be taken not to break down the glands too rapidly, as the large amount of decomposition products with the toxins of the disease thrown rapidly into the circulation sometimes produces severe systemic disturbances.

The consideration of the treatment of new growths, and more especially cancer and sarcoma, must necessarily be brief. The X-rays may be used in the treatment of new growths for its palliative, curative or anodyne effect. The

results of the X-ray treatment of sarcomas seem to point not to a curative but a retarding effect. For the better understanding of the cancerous conditions we may divide the subject into the epitheliomas or skin cancers and the subcutaneous cancers, including those which are beneath the tissues and cancers of the internal organs.

For most of the skin cancers X-ray treatment should be the treatment of election. Where there is no disease in the glands or other organs, treatment of a well-defined skin cancer by the X-rays is curative. Sufficient time has elapsed since the early reported cases to induce the belief that the cures are lasting.

Cancers of the tongue and mucous membranes are seldom successfully treated by the X-rays. In these conditions growth is very rapid, and death usually inevitable after any treatment. And it may be considered as an axiom, in X-ray therapy, the more chronic the disease the more likely the cure. At the present time and with our present apparatus and experience the cure of subcutaneous cancers appears very doubtful. Early excision still offers the best chance to cure, but it is in these cases that have been operated upon that much good can be done by radiotherapy subsequent to operation. Treatment of subcutaneous cancers by the X-rays prior to operation did not yield the results expected, but treatment of these cases after operation will forestall an oncoming recurrence and may possibly prevent it altogether. Here the results are most satisfactory. In the advanced cases of the disease—the inoperable cases—much can be done in prolonging life and in curing up ulcerations, retarding the disease, and controlling pain by systematic X-ray treatment.

JOHN A. LEE, M.D.

Radish, several species of herbs of the order *Cruciferae*. The common garden radish (*Raphanus sativus*) is thought to be a native of Asia, but is not known in a wild state. It is cultivated for its edible roots, which in various varieties may be red, white, gray, brown or black, and vary in form from turnip-shaped to parsnip-shaped. They reach edible maturity in from three weeks or less when forced. Radishes thrive best in rich, light, well drained sandy loam. Out of doors the seed may be sown as soon as the soil can be worked, since the plants are very hardy. The seeds may be dropped about an inch apart, covered an inch deep, in rows a foot asunder in beds by themselves, or, as in market garden practice, may be sown between slower-growing crops, such as carrots, cabbage or peas. Sometimes they are even sown with the seed of parsnips, onions and other crops that are either slow to germinate or that are very inconspicuous when they first appear. They then serve to indicate the positions of the rows, so that cultivation of the other plants may begin much earlier; they must then be removed promptly to prevent injuring the main crop. For succession, the seed should be planted at intervals of a week or ten days. Winter radishes are sown from midsummer to early autumn, and when cold weather arrives are stored in pits or cellars like other roots. Clean cultivation is essential. A Japanese species (*R. caudatus*) is popularly cultivated in Asia for its long pods which are eaten raw or pickled. It is known as the serpent or rat-tailed radish. The

pods are often a foot long. The roots are small, hard and inedible. The sea radish (*R. maritimus*) is more pungent than the garden species and is little known in American gardens. Horseradish (q.v.) belongs to a different genus, *Cochlearia*. Many of the insects which feed upon cabbage, turnip, mustard and related plants also feed upon the radish. The best known is the radish maggot which is the larva of a brown fly (*Phorbia brassicae*). The maggots tunnel in the fleshy part of the root and injure it for human food. Applications of fertilizers, especially quickly soluble ones, and rotation of crops have been recommended as preventives. Consult, Bailey, 'Cyclopedia of American Gardening' (New York, 1900-2).

Radistcheff, Alexander Nikolaievich, Russian author: b. Moscow 1749; d. there 1802. He was descended from a noble Russian family, and after spending several years at court as a page, was sent to be educated at the University of Leipsic. He returned to Russia in 1771, and obtained a position in the department of customs. He had been deeply impressed during his absence by the writings of the French philosophers of the time, and in 1790, under the influence of his liberal sentiments, he wrote his famous 'Journey from Saint Petersburg to Moscow,' patterned somewhat after Sterne's 'Sentimental Journey.' This work is a most striking picture of Russian serfdom as it existed at the time, and contains a plan of emancipation, all the more bold for its appearance in a period of reaction. The author was sent to Ilimsk, in the government of Irkutsk, by the Empress Catharine, but was allowed to return to Russia in 1796. He was made a member of the legislative commission in 1801.

Radium (from Latin, *radius*, ray), symbol Ra, discovered in 1898 at Paris by Professor Pierre Curie and Mme. Sklodowska Curie in collaboration with M. Bemont. It is the most important and most interesting of the radioactive substances which have thus far been found in uraninite or, as it is termed in popular parlance, pitchblende. (See PITCHBLEND.)

Radium, which resembles common table salt in appearance, is a new element having an atomic weight of 225. In its chemical and other characteristics, it resembles barium, with which it is closely allied and which latter substance has an atomic weight of 157.

Radium is a metal, and while it is never prepared in a metallic form, it readily could be so produced, although only at a great loss involving perhaps thousands of dollars, but it would not last in this form, being very unstable and, like sodium, immediately oxidized and destroyed. In the form of a chloride or a bromide, in which forms it is usually prepared, it lasts indefinitely without any apparent physical or chemical change. Professor Henri Becquerel has stated that if a square centimetre of surface was covered by chemically pure radium it would lose but one thousandth of a milligram in weight in a million years time. Similar statements have been made, by Professor J. J. Thomson and others, tending to show that, notwithstanding the enormous amount of energy given off by radium in producing its remarkable chemical, physiological, luminous, thermal, elec-

trical, and other effects, there is no appreciable loss in weight nor any microscopic, spectroscopic or chemical change in the original body.

Among the remarkable characteristics of this extraordinary substance may be cited the following:

It gives off three distinct types of rays named after the first three letters of the Greek alphabet, Alpha, Beta and Gamma. The Alpha rays constitute about 99 per cent of all the rays and consist of positively electrified particles. These were at first supposed to be uninfluenced by magnetism, but Rutherford has recently shown that with a powerful magnetic field about 30 per cent of the rays are deflected and in a powerful electric field as high as 45 per cent are deflected. The deflection is in the opposite direction to the Beta rays. The mass of the Alpha body is about twice that of the hydrogen atom. They have scarcely any penetrative power and are readily absorbed in passing through a sheet of ordinary note paper or a few inches of air.

The Beta rays, which are the most spectacular of the rays and have been given the largest amount of attention by investigators, consist of negatively charged particles or "corpuscles" approximately one two-thousandth the size of those constituting the Alpha rays. In every particular these rays resemble the cathode rays produced by an electric discharge inside of a highly exhausted vacuum tube, although they work at a higher velocity than the cathode ray particles. They are readily deflected by a magnet, discharge electrified bodies, affect photograph plates, stimulate strongly phosphorescent bodies and are of great penetrative power.

The Gamma rays are very few in number, so few in fact that they have received little attention thus far. They are almost impossible to detect save in a highly radioactive substance such as radium. They resemble in many respects very penetrative X-rays produced at the moment of the expulsion of the Beta or cathode rays. They are uninfluenced by magnetism, pass in straight lines at great speed and possess remarkably penetrative properties, even affecting a photograph plate through a foot of iron.

It gives off a gaseous emanation, as does thorium, which is also a powerfully radioactive substance. (See THORIUM.) The emanations possess all the properties of gases: diffusing through air and porous substances such as paper, they can be stored like ordinary gas and can be condensed at a temperature of liquid air, and are unaffected by chemical reagents.

It ionizes the air or makes the air (in fact, any gas through which it passes) a conductor of electricity.

It discharges negatively electrified bodies.

It is, according to Mme. Curie, the first example of a body which spontaneously charges itself with electricity.

It acts upon the chemical constituents of glass, porcelain and paper, giving them a violet tinge, changes white phosphorus into yellow, oxygen into ozone, affects photograph plates and produces many other curious chemical changes.

It imparts radioactivity to everything surrounding it. (See RADIOACTIVITY.)

RADIUM

It destroys the germinative power of seeds.

It likewise destroys various micro-organisms and checks the growth of others.

It has given encouraging results in the treatment of certain classes of disease, but it is too early as yet to state positively to what extent it can be used in medicine and surgery. Owing to its scarcity and high cost, but few have been able to experiment with radium, and insufficient time has elapsed to prepare specifications for its use or to state with positiveness what its limitations are in this field. It has produced paralysis and death in fish, mice, rabbits, guinea pigs, and other animals, and would undoubtedly similarly affect human beings. Professor Curie has told the writer that he would not care to trust himself in a room with a kilo (2.2 pounds) of radium, for it would destroy his eyesight, burn all the skin off his body, and probably kill him, and he has recently said that a single gram of chemically pure radium could destroy the life of every soul in the city of Paris, provided they were separately and properly exposed to its influence.

It retards the growth of certain forms of life such as larvæ, so that they do not pass into the chrysalis and insect stages of development, as their companions do; but remain larvæ.

It causes other forms of life, such as very young tadpoles, to become monstrosities or abnormalities. It causes the hair of mice to fall out, and they run about without a hair on them, and, if the radium is placed closer, the mice are paralyzed and killed. On the other hand, it causes a growth of the hair or fur of rabbits when they are exposed to radium placed at a proper distance.

It has produced partial paralysis in the "Torpedo Galvani," or electric ray, on a comparatively short exposure, so that it could no longer give its powerful electric shocks.

It has frequently caused serious burns and ulcers when placed near the flesh for a short time, the rays acting through the clothing of the person exposed, and, in fact, to a greater or less degree passing through everything, solids, liquids and gases, even through many inches of steel.

It is not affected by great extremes of heat and cold in respect to its radioactivity, but varies in the degree of its luminosity.

It gives off but little light, its luminosity being largely due to the stimulation of the impurities in the radium by the powerful but invisible radium rays.

It affects photographic plates placed in opaque envelopes, which plates, so protected, would not be affected even though exposed to bright sunlight for 24 hours, as ordinary light does not penetrate opaque substances. Ordinary light is also reflectable, refractable and polarizable, whereas the Becquerel rays coming from radium do not possess these characteristics. By reason of the foregoing the pictures of objects produced on the negative by radium and other radioactive substances cannot properly be called photographs; they are in reality radiographs.

It has a temperature, as discovered by Professors Curie and Laborde, of between five or six degrees Fahrenheit above its surroundings and will melt its own weight of ice every hour for an indefinite period.

It may prove ultimately that the alchemists of old were not so far wrong in their belief in the transmutation theory, for Sir William Ramsay and Professor Soddy have demonstrated that helium, one of the new elements discovered in the atmosphere by Professor Ramsay and which constitutes the gas most prevalent in the sun's atmosphere, is shown by the spectroscope to be present in the gaseous emanation from radium, and Professor Ramsay states that eventually the entire emanation turns into helium, proving, so he claims, that one element can change into another.

It constitutes an absolute test of the genuineness of a diamond, causing diamonds to phosphoresce strongly when brought near the radium, whereas imitation stones will glow but little, if at all.

It not only imparts radioactivity to cardboard, metals, etc., but such substances made radioactive on being placed near the radium can be stimulated by the vibrations from sunlight, burning magnesium, ultra-violet light, an electrical brush discharge, etc., so that the object will glow beautifully in the dark. Freshly fallen snow and rain and certain mineral springs and baths are radioactive; even the leaves of trees, blades of grass; in fact, practically everything in nature may be said to possess this property in some degree, and a fine wire charged with negative electricity of approximately 500 volts will become coated with radioactive properties, collected from the atmosphere, and this deposit can then be scraped from the wire and used.

It imparts radioactivity to anything adjacent to it, and the coating thus formed is so adhesive that water cannot wash it off, although it can be removed with ammonia.

It also imparts a beautiful carmine color to a flame in which it is burned.

It stimulates powerfully various mineral and chemical substances near which it is placed, and, substances such as willemite, sulphide of zinc, etc., in a powdered form, having a little radium mixed with them, are thus made to glow very brightly in the dark for an indefinite length of time, and there is promise in this direction of securing an efficient illuminating agent without flame and without appreciable heat.

It is found in a smaller percentage in pitchblende and other radioactive substances, according to Prof. J. J. Thompson, than the percentage of gold which is found in sea water.

It takes, says Professor Curie, 5,000 tons of uranium residues, that is, pitchblende, after the uranium has been extracted, to make a kilo (2.2 pounds) of radium, and this product by no means radium in its purest state.

It formerly took three months, and even now takes about one month, to work the process, and it costs about \$2,000 a ton to refine the uranium residues.

A bibliography of radium, even at this early date, would be very extensive; among the publications containing the most important contributions are *The Phil. Mag.*, *Comptes Rendus*, *Ann. der Physik*, *Revue Gen. des Sciences*, *Nature*, *Jour. de Phys.*, *Soc. Française Phys.*, *Bulletin*, *Chem. News*, *Phys. Ges. Verk.*, *Phys. Zeit.*, *Science Abstracts*, *Wien. Ann.*, *Ber. Dtsch. Chem. Ges.*, *Proc. Royal Soc.*, etc.

WILLIAM J. HAMMER,
Consulting Electrical Engineer.

P. Curie

M. Curie

THE DISCOVERERS OF RADIUM.

Ra'dius, the bone of the fore limb of vertebrate animals, which, as in man, when the arm is laid flat, with the palm upward, lies to the thumb side of the limb. This side is therefore termed the *radial* side of the limb, in contradistinction to the *ulnar* or opposite side, so named from the ulna or neighboring bone, which, with the radius, constitutes the forearm. See **ARM**.

Radius in geometry. See **DIAMETER**.

Radius Bar, or **Radius Rod**, one of the guiding-rods in a parallel motion, jointed to the connecting links, to counteract the vibratory motion communicated by the beam by guiding the links so that the head of the piston rod may reciprocate in a line sensibly straight.

Radius of Curvature. See **CURVE**.

Radius Vector. See **MATHEMATICS**.

Ra'dix. See **ROOT**.

Radom, rā'dōm, Russian Poland, (1) capital of the government of same name, 65 miles south of Warsaw, and one of the best-built provincial towns. Its special features are an ancient church and convent. Its manufactures are of tin, oil, vinegar and leather. Two fairs are annual attractions. Pop. 25,000. (2) The government covers an area of 4,708 square miles, and has a pop. of (1897) 820,363.

Radowitz, rā'dō-vīts, **Joseph Maria von**, Prussian statesman: b. Blankenburg, Germany, 6 Feb. 1797; d. Berlin, Germany, 25 Dec. 1853. He was of a noble Hungarian family, and in 1813 entered the Westphalian army as an officer. In 1823 he entered the Prussian service, and in 1830 became chief of the general staff of artillery and a leader of the anti-revolutionary party. He subsequently held diplomatic posts at Carlsruhe, Darmstadt, and Nassau, was the confidant and adviser of King Frederick William IV., and after the revolution of 1848 supported the efforts of Prussia to give a constitution to Germany. He wrote several works, mainly political, which include: 'Gespräche aus der Gegenwart über Staat und Kirche' (1846-51); 'Gesammelte Schriften' (1852-3); etc.

Radziwill, rād'zē-vil, ancient Polish family. Among its most famous members are: (1) Nicholas the Black, son of John the Bearded, and palatine of Wilna; d. 1567. King Sigismund Augustus gave him the command, in 1552, in the war against the Polish knights. He also commanded in the war against Russia in 1561. Having become a convert to the Reformation, he procured a translation of the Bible into the Polish tongue (Biblia swieta, Brzesc, 1563). (2) Christopher II., military governor of Lithuania and palatine of Wilna. b. 1585; d. 1640. After the death of Sigismund, in 1632, he undertook the defense of the Protestants at the Diet of Warsaw and obtained complete toleration for them. Enjoying the confidence of Wladislaw IV. he commanded in the war against Russia. (3) Boguslaw, Prince Radziwill, son of Prince James and Sophie Elizabeth, margravine of Brandenburg, was governor in Prussia, 1657-69, and rendered important services in endowments to universities and schools. (4) Charles, Prince Radziwill, palatine of Wilna and grand-commander of Lithuania: b. 1734; d. 1790. He was the enemy of Czartoryski and the Russians, and an adherent of the Saxon party. He was an ardent supporter of the Confederation of Bar,

and was several times exiled. For three years he was a member of the constituent diet at Warsaw. Consult 'Die historische Stellung des Hauses Radziwill' (1892).

Rae, rā, **John**, Scottish explorer: b. near Stromness, Orkney Islands, 30 Sept. 1813; d. London 22 July 1893. He studied medicine at Edinburgh, became surgeon in the Hudson's Bay Company's service in 1833, and from 1835 till 1845 was the company's resident surgeon at Moose Fort. In 1846-7 he made his first exploring expedition, covering 700 miles of the northern coast of America. He then went to London, and in 1848-9 accompanied Sir John Richardson in his Franklin search in the Mackenzie and Coppermine region. He conducted two expeditions in 1851, during the first of which he explored a large part of the coast of Wollaston Land. During the second he traveled a distance of over 5,000 miles in eight months, and explored much of the coast of Victoria Land. In 1853-4 he again conducted an expedition, and discovered the first traces of Franklin's fate, for which the party received the government grant of £10,000. He also proved King William's Land to be an island. He published 'Narrative of an Expedition to the Shores of the Arctic Sea in 1846-47' (1850).

Rae, **W. Fraser**, English author: b. 1835; d. 22 Jan. 1905. He was educated at Heidelberg and was admitted to the bar in 1861. Among his works are 'Newfoundland to Manitoba' (1881); 'Facts about Manitoba' (1882); 'Miss Bayle's Romance,' a novel (1887); 'An American Duchess' (1891); 'Egypt To-day' (1892); 'Biography of Sheridan' (1896).

Raeburn, rā'bērn, **Sir Henry**, Scottish painter: b. Stockbridge, near Edinburgh, 4 March 1756; d. there 8 July 1823. He was left an orphan at an early age, and was apprenticed to a goldsmith, who, perceiving his talent for drawing, encouraged him in his ambition to be an artist. The favorite portrait painter in Edinburgh at that time was David Martin, who was the only instructor Raeburn ever had. He formed his style, however, by copying in color, mezzotints from the paintings of Sir Joshua Reynolds, and while he learned the chiaroscuro of that master he never attained his almost Italian richness and solidity of coloring. His drawing was correct, but unfortunately acting under the idea that a portrait was to be viewed at some distance above the level of the eye, he foreshortened the forehead and brought forward the nostrils and lower jaw. Thus Sir Walter Scott complained that his portrait by this artist caused him to look "clownish and jolterheaded." Acting on the advice of Reynolds, Raeburn spent two studious years in Italy (1785-7) which resulted in a marked improvement in his coloring, which had previously been thin and undecided. Wilkie actually wrote from Spain that the execution of Velasquez reminded him of Raeburn. His 'Portrait of Mr. William Forsyth' in the New York Metropolitan Museum is a fair specimen of his style and there are two pictures of his in the Lenox Library. Another fine portrait may be seen in the Art Museum, Worcester, Mass. He confined his serious artistic efforts entirely to portraits and painted every eminent Edinburgh man of his day.

Raff, räf, Joseph Joachim, Swiss composer: b. Lachen, Switzerland, 27 May 1822; d. Frankfort-on-the-Main 24 June 1882. He was educated at Wiesenstetten in Württemberg and at the Jesuit Lyceum in Schwyz, and gained the notice of Mendelssohn and Liszt. In 1850 he removed to Weimar in order to be near Liszt, and his opera 'König Alfred' was shortly afterward produced at the Court Theatre there with great success. In 1877 he was appointed director of the Conservatoire at Frankfort, a position he occupied until his death. He was an indefatigable worker, his compositions numbering over 200, and his reputation rests chiefly upon his symphonies, among which are: 'Im Walde'; 'Lenore'; 'An das Vaterland'; etc. He was also very successful as a song-writer, and a notable composer of instrumental pieces, but his three operas were less successful. Though not confining himself to any one style of composition he was a supporter of the Wagner school.

Raffaello, rä-fä-ël'lō. See RAPHAEL.

Raffia. See FIBRE.

Raffinose, the name given a plant sugar derived from the particular species of eucalyptus trees growing in Tasmania.

Raffles, räf'lz, Sir Thomas Stamford, English colonial administrator: b. at sea, off Point Morant, Jamaica, 5 July 1781; d. Highwood, near London, England, 4 July 1826. He was employed in the East India House as a clerk when 14, soon attracted attention by his ability and in 1805 was appointed assistant secretary at Penang. He mastered the Malay language while on the voyage and in 1807 was appointed secretary and registrar of the recorder's court. He visited Malacca in 1808 and in 1810 went to Calcutta where he met Lord Minto, the governor-general, and by his advice the expedition against Batavia was fitted out in 1811. He accompanied Lord Minto to Java in that year and after its capture from the Dutch became its lieutenant-governor, an office which he held for five years. His administration was eminently wise and successful; he retained the Dutch colonial laws, but abolished forced labor and instituted marked improvements in taxation and the administration of justice. He returned to England in 1816 when the island was given up to the Dutch, was knighted and commissioned by the prince regent to proceed to Holland to confer with its king in regard to the government of Java. In 1818 he was appointed governor of Benckulen in Sumatra, where he found many abuses existing. He abolished slavery, reorganized the government of the colony, founded schools, and otherwise greatly improved the condition of the island. He explored with Joseph Arnold the interior of the island and discovered the great fungus named in their honor *Rafflesia Arnoldi*. Ill health compelled his return to England in 1824 and on the voyage the ship caught fire, destroying his natural history collection, manuscripts, drawings and notes valued at \$100,000. He held no further public office. He published: 'History of Java' (1817); and 'Malayan Miscellanies' (1820-2). Consult: Lady Raffles, 'Memoir of Sir T. S. Raffles' (1830); Egerton, 'Sir Stamford Raffles' in 'Builders of Great Britain' series.

Raffle'sia, an East Indian genus of parasitic plants, reduced to apetalous dioecious flowers, and named after Sir Stamford Raffles, the discoverer. *R. Arnoldi* was the first species discovered, in Sumatra. It is a gigantic flower, springing from the roots or stems of *Vitis* (*cissus*), three feet in diameter, and consisting of a globular central cup, containing either the ovary, or the numerous stamens, crowned by a ring, and the five-lobed calyx, fleshy, and flesh-colored, blotched with pink and yellow inside, and with brownish or bluish scales exteriorly. The whole flower sometimes weighs 15 pounds. It remains expanded for a few days only, and then decays, emitting a putrid odor that attracts carrion-loving flies, which probably assist in cross-fertilization. The fruit is a brown, rough surfaced nut, holding innumerable seeds. Certain Javanese species are valued there as powerful styptics.

Rafinesque-Schmaltz, rä-fē-něsk' smältz, Constantine Samuel, American botanist: b. Galatz, Turkey, 1784; d. Philadelphia, Pa., 18 Sept. 1842. He was of French-German parentage and was sent to America in 1802 where he made botanical investigations in Pennsylvania and Delaware and in 1805 returned to Turkey with botanical specimens. While sailing for the United States in 1815 he was shipwrecked off the coast of Long Island and lost his collection of 20 years. He settled permanently in the United States in 1815, and was made professor of botany in Transylvania University, Lexington, Ky., in 1818. Later, after lecturing in various places, he removed to Philadelphia. He was a man of wide learning, but his work is in many instances rendered confusing by his insatiable desire for novelties, and though evincing keen insight is frequently inexact. His publications include: 'Ancient History, or Annals of Kentucky' (1824); 'Medical Flora, etc., of the United States' (1828-30); 'A Life of Travels and Researches in North America and South Europe' (1836); 'Pleasures and Duties of Wealth' (1840); etc.

Raft, a floating platform, usually composed of wooden logs or planks, fastened together by nails, spikes or cordage, and used either as a vehicle of travel and for the carriage of goods, or more generally for the purpose of transporting by river, lake or sea the materials composing the raft from the place of its construction to a market for sale. In all probability the raft was the first human method of travel on water, next to floating on a large branch or tree-trunk, the use of which would naturally suggest the raft, just as a raft, with sail of skin or other material raised to catch the wind, would suggest the first rude sail boat or ship. Rafts have been in use in all historic ages, and doubtless far back in the prehistoric period, but they reached their most general use after the settlement of North America, when the vast forests were being cleared by settlers, and the raft offered almost the only method by which the pioneer on the Ohio or Mississippi could reach the settlements on those rivers, dispose of his surplus products, and buy some of the comforts and perhaps luxuries to be obtained in the towns. The steamboat has almost entirely done away with the raft as a means of travel, but rafting is still the chief method of conveying

the lumber product of northwestern forests to market, and immense rafts are sometimes sent by sea from Maine to New York or Boston. On the Pacific coast also the rafting business is most extensive. In the fall of 1902, a monster raft 700 feet long, 53 feet wide, 12 feet from the water's edge to the top, and drawing 22½ feet of water was safely towed 700 miles from Columbia River to San Francisco. The logs were 120 feet long, and from 12 to 20 inches in diameter, and there were in all 7,000 pieces, valued at \$60,000. The construction of a raft of this size is a vast undertaking. A great "cradle" of heavy timbers is built on a slough connected with the Columbia River. A row of piling is driven in deep water, and the frame of the cradle floats up and down on the row of piling, and is held in place by it. A large scow with a derrick is anchored beside the cradle. Log-booms or small rafts are towed to it, and the logs are lifted by the derrick into the cradle, where they are fastened with chains and cables, from 80 to 100 tons of chain being used on one raft. When the raft is finished the keys that held the parts of the cradle together are drawn, the side of the cradle is pulled away, and the raft floats out on the water. Tugboats draw it into and down the Columbia, and out to sea on its voyage to the Golden Gate.

Fire-rafts have been used in ancient and modern wars to destroy an enemy's vessels, but since navies have been built of iron and steel, the fire-raft is becoming obsolete.

Ragatz, rä'gäts, Switzerland, a fashionable Spa in the province of St. Gall on the Tamina, celebrated for its hot springs, mineral waters, and scenery. Pop. (1900) 1,862. See PFEFFERS.

Ragged Robin. See LYCHNIS.

Ragged Schools, a name given in Great Britain to those institutions supported by voluntary contributions for the education of neglected children and the consequent prevention of juvenile crime. The idea of forming such schools was due to a Portsmouth cobbler, John Pounds, who about 1819 began to take in the ragged children of the district in which he lived and teach them while he was at work. This he continued till his death in 1839. The success of the plan caused a number of more influential persons to take the matter up, and in 1838 a ragged Sunday-school was opened in London. In 1841 the first feeding-school, in which the children are not only educated but kept and fed for the day, was started in Aberdeen. What gave a greater impetus than anything else to the ragged school scheme was Dr. Guthrie's 'Plea for Ragged Schools,' published in 1847. It had an immense circulation, and was followed by the extension of the system to every considerable town in the kingdom. The name ragged schools was first adopted in 1844. Owing to the education acts, and especially the introduction of compulsory school attendance and abolition of fees, many of these schools were absorbed by the school-boards, and altogether they may be said to be a thing of the past.

Raghuvamśa, rä-g-hoo-vān'sha, one of the two epics of the Sanskrit poet Kālidāsa (q.v.). Its subject is the legendary history of the solar kings, or kings descended from the sun. See SANSKRIT LANGUAGE AND LITERATURE.

Ragie, a grain. See ELEUSINE.

Raglan, Fitzroy James Henry Somerset, LORD: b. 30 Sept. 1788; d. Sebastopol 28 June 1855. In 1804 he entered the army and in 1807 served on Wellington's staff in the expedition to Copenhagen, while throughout the Peninsular campaign he served as military secretary. In 1814 he acted for a short time as secretary to the embassy at Paris, and from January to March 1815 was minister plenipotentiary there. At Waterloo he lost his right arm. From 1819 to 1852 he was military secretary to the Duke of Wellington, in 1852 became master-general of the ordnance and in October of that year entered the House of Peers as Baron Raglan. He was commander of the English forces in the Crimean war, where he suffered much from the early failures of the campaign and from the hostile criticism of the inefficient commissariat arrangements. Consult Kinglake, 'Invasion of the Crimea.'

Ragman Rolls, documents containing a record of the acts of allegiance extorted by Edward I. of England from the nobility and gentry of Scotland in 1291-2 and 1296. The document was delivered back to the Scotch along with other records and muniments in 1329 in terms of the Peace of Northampton when the independence of Scotland was formally acknowledged. It is now deposited in the British Record Office.

Ragnarök, räg''na-ek', in Scandinavian mythology, the day of doom when the present world will be annihilated, to be reconstructed on an imperishable basis. The title of the concluding portion of Wagner's great operatic trilogy 'Götterdämmerung' is a translation of this word. In that work is depicted the downfall of Woden and the gods and the triumph of perfect human love. William Morris also treats this subject in his 'Sigurd the Volsung.' 'Ragnarök' is the title of a novel by Ignatius Donnelly.

Ragout, rä-goo', a French dish prepared of meat or fish stewed with vegetables, and highly seasoned.

Ragozin, rä-gō'zën, Zenäide Alexeievna, Russian-American writer: b. Russia 1835. She traveled widely in Europe and in 1874 came to the United States. She is a member of the leading American and European literary societies, and has achieved a wide reputation as an author. Her most important books are: 'The Story of Chaldea' (1886); 'The Story of Assyria' (1887); 'The Story of Media, Babylon, and Persia' (1888); 'History of the World'; 'Siegfried, the Hero of the Netherlands' (1898); 'Roland, the Paladin of France' (1899); 'Salamambo, the Maid of Carthage' (1899).

Rags, though valueless for most purposes, are yet of great importance in the arts, particularly in paper making. Woolen rags of a loose texture, and not too much worn, are unraveled by means of machinery, and mixed up with good wool, to form what is known as "shoddy," with which cheap woolen goods are made. Large quantities of rags are imported to the United States from Great Britain and the continent of Europe.

Ragueneau, räg-nō, Paul, French missionary and explorer: b. Paris 1605; d. there 3 Sept. 1680. He joined the Jesuit order, and went to

Canada in 1636 to work among the Indians, first visiting the Hurons. In 1640 he made an unsuccessful attempt to secure the release of French prisoners from the hostile Iroquois. Becoming the head of the Jesuit missions in Canada in 1650, he brought the remnant of the Hurons to Quebec to escape the Iroquois. On a visit to the Onondaga tribe of Iroquois he nearly lost his life. His chief success was with the Hurons, with whom he labored until 1666, when he returned to France and acted as agent for the Canadian missions. He wrote 'Vie de la Mère St. Augustine, religieuse Hospitalière de Quebec en la Nouvelle France' (1672); 'Relation de ce qui s'est passé de plus remarquables des Missions des Pères de la Compagnie en la Nouvelle France' (1647-57), the latter work covering the years 1645-52 and 1656-7. Consult: Parkman, 'The Jesuits of North America' (1867); 'The Jesuit Relations' (1896-1901).

Raguet, rä-gä', **Condy**, American political economist: b. Philadelphia, Pa., 28 Jan. 1784; d. there 22 March 1842. He was educated at the University of Pennsylvania, studied law, and later entered upon a commercial career. He went to Santo Domingo in 1804 as supercargo on a vessel and made a second voyage to that island in 1805. In 1806 he went into business on his own account and was eminently successful, amassing an immense fortune and playing an important part in the commercial affairs of the day. In 1812 he was active in providing for the defense of Philadelphia against the expected attack of the British fleet, and in 1815 was elected to the State legislature where he subsequently served in both houses. He was appointed United States consul at Rio Janeiro in 1822 and in 1825 became *chargé d'affaires* to Brazil, an office he occupied until 1827. After his return to the United States he edited several journals devoted to free-trade doctrines, among them 'The Free Trade Advocate' in 1829; 'Examiner' in 1834-5; 'The Financial Register' in 1837-9; he also published two small volumes relating to Santo Domingo; 'Principles of Free Trade' (1835); 'On Currency and Banking' (1839); etc.

Ragusa, rä-goo'sä (Slavic, DUBROVNIK), a seaport town of southern Dalmatia, Austria-Hungary, on a peninsula projecting into the Adriatic. It lies at the foot and on the slopes of Monte San Sergio and its streets rise in terraces from the Corso, the principal thoroughfare, which traverses the centre of the city. There are old walls flanked with towers and a fort erected during the French occupation in the beginning of the 19th century. Among the notable public buildings are the cathedral dating from the first years of the 18th century; the new Greek church; the older churches of the Franciscans, Dominicans, and Jesuits; the town-hall, anciently the governmental palace, completed in the early part of the 15th century after nearly a hundred years in building, and forming a magnificent example of the Gothic-Venetian style; and the Dogona, of the same architectural type. The industrial interests of the town comprise chiefly manufactures of silk, leather, and liqueurs. The coasting trade is important, but owing to the shallowness of the harbor, centres chiefly at Gravosa, some four miles to the north. The population in 1900 was 13,194. Ragusa was

founded in the 7th century of our era by refugees from the ancient Epidaurus, now known as Ragusa Vecchia, when that city, whose origin goes back to the 6th century before Christ, was destroyed by the Slavs. Ruled in turn by the Byzantines, the Venetians and the Hungarians, it acquired in the 13th and 14th centuries, through trade and unscrupulous diplomacy, lordship over a territory of some 750 square miles and maintained its existence as an aristocratic republic, paying tribute, after 1440, to the Turks. The prosperity of the town was undermined by several epidemics in the 16th century and by repeated earthquakes of which that of 1667 was the most disastrous. In 1806 Ragusa was occupied by the French, two years later the republican form of government was abolished, and in 1809, with the rest of Dalmatia, it was annexed to the Illyrian kingdom. In 1814 it passed to Austria. The see of Ragusa was founded in 980, and from 1121 to 1831 it was the seat of a Roman-Catholic archbishop. So well known were its trading vessels in former times that our word *argosy* is derived from the name of this port.

Ragusa, a town of Sicily, in the province of Syracuse, on the mountain stream Erminio, some 30 miles west-southwest of Syracuse. It has considerable manufactures of cotton and other textiles, oil, furniture, and asphalt and carries on an important trade in corn and wine. It comprises two communities, Ragusa proper with a population in 1901 of 31,922, and Ragusa Inferiore with 8,550 inhabitants. Ragusa is supposed to be the ancient Hybla Heræa.

Ragwort, any of various composite weeds of the genus *Senecio*, now common in all parts of the world. These coarse, yellow-flowered, pubescent plants are allied to the thistles, and some of the score of American species are known as squaw-weed, ragwort, and butter-weed, and in England as groundsel. See *SENECIO*.

Rahl, rä, **Karl**, Austrian painter: b. Vienna 13 Aug. 1812; d. there 9 July 1865. At 19 he won a prize at the Vienna Academy and then started on his first tour among the art centres of Germany, Hungary, and Italy. He made his home in the last named country from 1836 to 1843, studying especially the painters of the Venetian and Roman school, from whom he derived the grandeur of conception and noble coloring for which his works are distinguished. In 1846, after two years' residence as a portrait painter in Vienna, he resumed his travels and practised his art with success and profit in Holstein, Paris, Rome, Copenhagen, and Munich. Among his historical paintings of his first period are 'The Finding of Manfred's Body'; 'Manfred's Entrance into Lucera'; 'The Catacombs during the Persecution' (in the Hamburg Gallery and a replica in the Berlin National Gallery). He was appointed professor in the Berlin Art Academy in 1850, but his political opinions were extreme and violent and he was compelled to leave the city. The private school which he thereupon opened became the most important seminary of painting in Austria. He meanwhile applied himself to much decorative work, as is testified by the painted façade and vestibule of the church in the Old Meat Market at Vienna, the four compositions from the Greek

heroic age, and the 'Four Elements' in the palace of Baron Sina. In 1864 he painted in the Museum of Arms a series of allegorical figures of heroic size. To this period belong his fresco, 'A Maid from Foreign Lands'; and the designs for a ball-room in Oldenburg Castle and 'Incidents of the Argonautic Expedition.' His last works consisted of designs for the decoration of the New Opera House at Vienna. These were executed by his pupils after his death. He unites in his pictures the rich coloring of Rubens and Titian with a harmony of grouping monumental in its impressiveness. Yet his handling of form inclines to coarseness and exaggeration. Among the most eminent of his pupils were Bitterlich, Eisenmenger, Lotz, Gripenkert, Gaul, and Than. Consult: George-Mayer, 'Erinnerung von Karl Rahl' (1882).

Ráhu, rá'hoo, in Indian mythology, the demon who is imagined to be the cause of the eclipses of sun and moon. Rahu, having stolen of the nectar of immortality, was caught and beheaded before he swallowed the divine stuff. The head thus became immortal, and ever afterward followed the sun and moon. When it occasionally caught them an eclipse resulted.

Rahway, rá'wā, N. J., city, in Union County; on the Rahway River, and on the Pennsylvania railroad; about 20 miles southwest of New York city. It is a residential city, and its clean, well-laid-out streets, its parks, and fine residences make it an attractive suburb. It has considerable manufacturing interests; the chief establishments are chemical works, printing houses, shirt factories, lace curtain factories, felt mills, steel works, carriage and music box factories. There is a large trade in manufactured articles, fruit, and vegetables. It has a high school, public and parish schools and a library, which has about 16,000 (1904) volumes. Pop. (1890) 7,105; (1900) 7,935.

Rai Bareli, rī bā-rā'le, India, (1) headquarters of a district of the same name, on the banks of the Sai, 48 miles southeast of Lucknow. It has a spacious fort, a magnificent palace, four fine mosques, and the tomb of Nawab Jahan Khān. Pop. 18,798. (2) The district of Rai Bareli forms a part of the Lucknow division, and has an area of 1,751 square miles. Pop. (1901) 1,033,948.

Raiatea, rī-ā-tā'ā, Polynesia, an island of the Society group, northwest of Tahiti; area, 75 square miles. It is mountainous (3,400 feet), but fertile, and traversed by many streams. The chief products are cotton and copra. Pop. (Protestant) 2,300.

Raibolini, rī-bō-lē'nē, **Francesco**. See **FRANCIA**, **FRANCESCO**.

Raiffeisen, rīf'i-zēn, **Friedrich Wilhelm**, German economist; b. Hamm, near Coblenz, Germany, 30 March 1818; d. 11 March 1888. He entered the army in 1835, but was compelled by ill health to withdraw and then entered the civil service. During the agricultural troubles of 1846-7 he perceived the difficulty with which the small landholder procured credit and he conceived the idea of establishing small mutual credit associations which freed the farmer from the exorbitant rates of the usurers. His first efforts were at Heddersdorf and Wyer-

busch and he then proceeded to extend the operation of the plan throughout Germany. In 1866 he broke down from overwork and retired for a time from public service. In 1878 he founded the 'Landwirtschaftliches Genossenschaftsblatt' at Neuwied. He lived to see his plan in successful operation in Germany, Austria, Switzerland, and Italy. He wrote: 'Instruktion zur Geschäfts- und Buchführung der Darlehnskassenvereine' (1869); 'Kurze Anleitung zur Gründung von Darlehnskassenvereinen' (1888); etc.

Raikes, rāks, **Robert**, English founder of Sunday schools; b. Gloucester, England, 14 Sept. 1735; d. there 5 April 1811. He succeeded to his father's business as editor and publisher of the Gloucester 'Journal' in 1757 and used its influence in exposing certain prison abuses in his native town. In 1781 he founded several Sunday schools which he engaged needy women to teach at a shilling a day, and succeeded in inducing the attendance of the children of the city. In 1803, largely through his efforts, the Sunday School Union was founded. Consult: Lives by Gregory (1877), and Eastman (1880); Harris, 'Robert Raikes: The Man and his Work' (1899). See **SUNDAY SCHOOLS**.

Rail Sections as Engineering Structures and Their Correlations to Equipment and Operation of Railroads. It is what a rail section can do, its combined stability, efficiency, and capacity with the equipment for carrying the loads, which determine its status and relative importance as an engineering structure. A rail section is heavy at the present time, of which sufficient for a mile of track equals or weighs more than the passing locomotive.

The installation of the railroads in the United States from 1826 to 1833 was usually with strap-iron rails, forming the bearing surface for the wheel treads, and guide to the flanges, laid on wooden or stone stringers as the girders.

The engines were of the four-wheel type, short wheel bases, and rode unsteadily over the light tracks. The driving-wheel loads, at first intended not to exceed 1,700 pounds, when increased to 4,000 pounds injured the light structures, at speeds of 10 to 15 miles per hour.

John B. Jervis, chief engineer of the Delaware & Hudson Canal Company's railroad, completed in 1829 the superstructure of strap-iron rails on wooden stringers, designed for the transportation of coal by steam-engines, from the mines to the canal at Honesdale, Pa.

Three engines were constructed in England, under directions not to exceed 1½ gross tons per wheel, but were heavier as built. The "Stourbridge Lion," 8 Aug. 1829, made only a short trial trip, and proved too heavy for the structure, and locomotives as motive power were abandoned.

The track proved adequate for the transportation of about 1,000,000 tons of coal annually, for several years, under the designed static wheel loads.

Mr. Jervis was the chief engineer of the Mohawk and Hudson Railroad in 1830, and 9 Aug. 1831 made the successful trial trip with the locomotive De Witt Clinton and passenger train. The superstructure was strap-iron rails 2½ inches wide, 9/16 of an inch thick, the upper corners rounded to a width of 1⅞ inches, and

RAIL SECTIONS

laid central upon 6 x 6-inch pine stringers, supported by stone blocks, each of two cubic feet, spaced three-foot centres, and set upon broken stone foundations, for inflexible supports as for buildings. This theory Jervis discarded in 1832 for that of the elastic roadbed.

The De Witt Clinton weighed 6,758½ pounds, and the John Bull, made by Robert Stephenson & Company, Newcastle-on-Tyne, England, weighed 12,742 pounds, of which 8,745 pounds were upon the pair of driving-wheels, which proved heavy for the superstructure and rode unsteadily over the track, and seldom used as received.

Mr. Jervis, in 1832, designed his four-wheel "leading and guiding truck," and substituted it for the front pair of carrying wheels of the engine, which extended the wheel-base and gave it lateral and vertical flexibility for ease of locomotion.

The truck, supporting the front of the engine, and the one pair of drivers the rear, subdivided the total load for distribution, and used a part to stiffen and strengthen the track for the driving-wheel loads, which was the inception of this valuable principle of American practice. A second pair of drivers was added, for greater adhesion, making the type of the American locomotive, which could now cross the mountain divides without inclined planes, a requirement for railroad extension and operation.

The prototype of the present tee sections, to be rolled as one piece and spiked directly to the wooden cross-ties or stone blocks, was designed by Robert L. Stevens in 1830, and laid on the Camden & Amboy Railroad in 1832. It was rolled in Wales, in 16-foot lengths, fished by 6-inch riveted two-hole plates, was 3½ inches high, 3¼ inches base, head 2⅞ inches wide, and weighed 39 9/16 pounds per yard; therefore was expensive, and the principles of construction not copied generally until after 1840, when it had demonstrated its value.

The two problems, evolution of the locomotive and of the rail section, were being solved at the same time, an improvement in either aiding the other, owing to the correlations which exist between them.

The strap-iron rails served to develop practical locomotion only, as about 4,000 pounds static driving-wheel loads were their limit, the spikes drawing or breaking, and failed to hold the iron to the wooden or stone stringers, as mechanical structures, and frequently the facing ends of the rails ("snake heads") sprang up above the centre of the following wheel and curled through the floor of the car, impaling passengers in their seats.

Sundry types of sections for iron rails, including Birkinshaw's "fish-bellied," and the Clarence pattern, set in chairs, compound forms of two or three pieces, were tried with the strap-iron rails, and by or before 1844 the most efficient iron tee sections became the principal reliance for service until 1863, the advent of Bessemer steel.

The compound rails failed mechanically after a short use. The best quality of iron rails, in light sections, rendered some years of service, until the static driving-wheel loads began to exceed 7,000 pounds. Before they had reached 10,000 pounds, lamination and exfoliation of the iron in the bearing surface were rapid, owing

to its limited and inadequate physical properties of cubic elasticity.

The pile of iron for the rail was formed of several slabs or pieces, put into a furnace and brought up to a welding heat, with the expectation that complete union would occur between all of the pieces in rolling. This did not take place, and the cinder which was in each bar rolled out more as a bundle of fibres in the section, preventing the formation of a solid homogeneous structure. The linear elasticity was sufficient as a girder, but deficient in cubic elasticity for the metal in the bearing surface.

The manufacture and use of heavier and stiffer sections of iron, for smoother and more stable tracks, caused such rapid wear of the rails that many companies returned to the use of lighter sections. This was a check to the extension and development of transportation for the country.

The introduction, in 1863, of light rails of Bessemer steel, a product more homogeneous and solid than iron, furnished a metal which, in the bearing surface, wore well, exceeding the life of 10 to 15 iron rails. This in a few years reduced operating expenses and enabled the extension of railway systems to new territory.

The cost of the steel limited the rails to light and limber sections. They were inefficient as engineering structures, and did not permit the desired enlargement of the locomotives to overcome the resistance of heavier trains, and meet the demands and requirements of transportation.

The maximum static load per driving-wheel in 1876 was about 13,000 pounds for some of the largest passenger engines, but three times greater than it was upon the strap-iron rails.

I invented and constructed my Dynagraph in 1874, to measure train resistance, and observed upon the Lake Shore & Michigan Southern, Baltimore & Ohio, Philadelphia, Wilmington & Baltimore, Boston & Albany, and the New York Central & Hudson River railroads that on new rails well surfaced the resistance was less than upon worn rails with low joints, the topographical conditions being the same.

A test was made of a passenger train, in 1878, on the New York Central & Hudson River Railroad, of 9 cars, 300 tons weight, at 51 to 52 miles per hour; the resistance was 11½ to 12 pounds per ton, only two thirds of that estimated by the English formula of Clarke. These were valuable facts to establish, not only as to the amount of the train resistance, but to one of its elements, for on the smoother track the resistance for every wheel was reduced, by rolling forward with less vertical undulations and shocks.

A sphere moving over a perfect plane in a straight line, irrespective of speed, theoretically would not do work for or against gravity, applies in principle to a moving car-body or wheels on the rails. Tracks of true planes on steam railroads are not expected to be realized, yet it was necessary to investigate their condition and measure the undulations on the light steel rails, to ascertain what was required to add to their efficiency and commercial value as engineering structures. The investigations of the condition of the track were made by the complete instruments I designed in 1880 for my Track Indicator. A special 6-wheel truck, of 11-foot wheel base, was made, to carry one end

RAIL SECTIONS

of the 50-foot car which contains the recording mechanism. The total load upon the truck is 19 tons, and the outer wheels act as the datum plane, while the middle wheels indicate the surface undulations of each line of rails, upon the moving band of paper, on a scale of one inch per 50 feet of track which is sufficient to show the detail of each rail. The vertical scale is full size.

The theory is, that if the running surface of the rail in its general depression under the truck is smooth, the recording pen would draw a straight line; if not, its deviation.

The gauge of track, speed, and distance, are measured, while the sections, mile posts, and stations, are located as they are passed.

The undulations are summed up automatically into feet and inches per mile, which furnish the data for the condensed diagrams, and show on a scale of 1/4 of an inch per mile the comparative condition of the track. These were commenced in 1881, and annually repeated exhibit the reduction in undulations, by the transition from the light and limber sections to the heavier and stiffer rails, as engineering structures, and also that the static driving wheel loads have nearly doubled in the meantime.

Paint is ejected automatically on the rails, for the trackmen, where the deflections exceed 1/8 of an inch.

The inspections of the track on the early steel sections indicated that the rails on all the different railroads had characteristic permanent sets, which proved that the mechanical elements of stiffness of the 4 or 4 1/2-inch sections were insufficient for the wheel loads. The trackmen were unable to maintain the track and prevent sets taking place in the rails, and rapid cutting of the cross-ties under the rail seats. The joints were low, the facing ends of the rails cut out, which gave shocks to every passing wheel, while the undulations under the wheel loads of the Track Indicator recorded from 6 to 12 feet per mile.

The original and condensed diagrams of over 10,000 miles of track were measurements and new data, to study the action and requirements of a section in the track, and in 1883 I designed the pioneer 5-inch 80-pound steel rail, for the New York Central & Hudson River Railroad, and in 1884 commenced to replace their 4 1/2-inch 65-pound rails. With 15 pounds or only 23 per cent more of metal, the section was increased in stiffness 60 per cent and in strength 40 per cent, and with a head 2 11/16 inches in width enforced the resultant of the passing wheel loads by their treads to hold the rails in a vertical position on the cross-ties, checking the rolling out and spreading of the gauge, which augmented the running stability of the equipment.

The 80-pound rails made a stiffer, stronger and smoother track than the former 65-pound and were soon followed by the Pennsylvania and the other railroad companies' adoption of 5-inch 80-pound or heavier sections.

The augmented 60 per cent in stiffness and 40 per cent in strength, with the advantageous correlations existing between them and the equipment, enabled nearly doubling the axle and total loads of the locomotive and cars on the same roadbed. It marks a distinct epoch in the progress of transportation.

Mr. William Buchanan, general superintendent of motive power, New York Central & Hudson River Railroad, designed his famous locomotive, No. 870, in 1889, with 40,000 pounds upon the engine truck, 80,000 pounds upon two pair of driving wheel axles, and 80,000 pounds upon the tender when loaded with coal and water, which made the first 100-ton locomotive. These weights did not disturb the track on the stiffer rails as the lighter axle loads had upon the former limber rails. On November 30, 1891, the Empire State Express was installed, the fastest long distance train ever attempted, which still maintains its prestige, as a demonstration and educator of practical fast speeds on stable track.

The running time from New York to Buffalo, 440 miles, was 8 1/2 hours, including 3 stops, 2 changes of locomotives, and 28 slow downs. In 1895 the schedule time was reduced 15 minutes. The achievement was of interest to the railroad world as an accomplishment of what had been considered previously impossible. The practical effect of the stiff rails has been the construction of larger and more powerful locomotives and an increase of speed on railroads, as shown by statistics. The Twentieth Century Limited, on the New York Central & Hudson River Railroad, and the Pennsylvania Special on the Pennsylvania Railroad, are now running from New York to Chicago and return each way in 18 hours.

The mechanical properties of stiffness and strength of a section are secured in the design for a given height and weight of metal by distributing as much of it in the head and base as far from the neutral axis for the longitudinal stresses as requisite for the relations of the bearing surface, guide and girder, denoted in Fig. 2.

The mechanical properties of different sections, are ascertained and compared by their respective moments of inertia and moments of resistance, and in the higher and heavier sections they increase in a faster ratio than the weight, and cost,—an engineering and economic advantage. See Table No. 1.

The different weights of the sections have from 40 to 45 per cent of the metal in the

TABLE NO. 1.

| Weight of Section in lbs. | Height in inches. | Width of Head inches | Moment of Inertia 4th Power inches | Moment of Resistance cubic inches | Bending Moments carried per Section for 20,000 lbs. Unit Fiber Strains inch-pounds. |
|---------------------------|-------------------|----------------------|------------------------------------|-----------------------------------|---|
| 60 | 4.0 | 2 1-4 | 12.0 | 6.7 | 134,000 |
| 65 | 4.5 | 2 3-8 | 16.0 | 7.8 | 156,000 |
| 80 | 5.0 | 2 11-16 | 26.0 | 10.5 | 210,000 |
| 80 | 5-18 | 2 21-32 | 28.5 | 11.4 | 228,000 |
| 100 | 6.0 | 3.0 | 48.5 | 16.6 | 332,000 |

RAIL SECTIONS

head, 37 to 40 in the base, and 20 to 23 in the web. The bearing surface is crowned with a radii of 12 or 14 inches, while the upper corner radii are 5/16 or 3/8 of an inch. The fishing angles of the head and base are 13 or 14 degrees, according to the design—the latter being the best to take up the wear of the splice bars. The web is joined to the head, in the best designs, by fillets of 1/2 inch radii.

The increased mechanical element of stiffness of rails lessens the deflections for a given load, while the strength reduces the unit fibre strains, therefore augments the capacity for larger bending moments and better distribution of the wheel effects to the cross-ties and ballast; but the wheel contact pressure intensity per square inch in the bearing surface is increased.

Standard sections of given weights, varying by increments of 5 pounds per yard, have been designed, with definite mechanical properties, and are manufactured as commercial products. My standards consist of 15 sections of 50 to 105 pounds per yard. There are three duplicate weights, but of different mechanical properties.

The 80- and 100-pound for main lines are in most general use, and the 65, 70, and 75 for branch lines, though the 80-pound will soon be a requisite. The New York Central & Hudson River Railroad commenced to lay my 6-inch 100-pound section in 1892, and that weight has become the standard for the Eastern trunk lines.

The A. S. C. E. standards are from 20 to 100 pounds per yard. The English standards for flat-bottom sections are of the same weights, for use in India.

"Bull Head" sections are standards for England.

The superstructure of the track, for American, English, French, and German steam railroads, is flexible, on an elastic roadbed as the foundation, and under the area of the wheel bases of the locomotives and cars to be loaded as uniformly as possible, by pressures which can be sustained.

and their generated forces, until the total resistance equals their effects.

The ballast and roadbed are compressed from one fifth to one third of the total amount of the temporary subsidence of the rail, and the latter is affected for a depth of 12 to 20 feet, according to its material, construction, and stability.

The rails are loaded only by the rolling wheel contacts, which bend them downward under the wheels, as indicated in Fig. 1—the positive bending moment—while in the wheel-spacing the flexure is upward—the negative bending moment; shearing stresses connecting the bending moments at the points of flexure.

The rail section therefore resolves and distributes its wheel-load effects by longitudinal components of stress, and produces compression in the metal above the neutral surface directly under the wheels, and below tension. Either side of the wheels in the spacing the stresses are reversed at the points of flexure, the wheel-space controlling the span of the bending rail more than that of the cross-ties. See *Stremmatograph Test No. 257*.

The strain in the metal of the rails is continuous for the entire wheel base of the locomotive, and not discontinuous per wheel. Comparisons for precision of the stresses under locomotives of the same or different types must include the total effects from all of the wheels as though distributed from their centres of gravity. See *Test No. 257*.

The tests of the unit fibre strains upon the same track show that reducing the wheel-spacing decreases the total bending moments, and distributes the load more favorably upon the foundation. This is confirmed in practice by the excellent results by the Ten-wheel, Pacific, and Consolidation types of engines.

Three Essential Principles of the Rail Section as an Engineering Structure.—First: The top as the bearing surface for the rolling wheel contacts.

Second: The side of the head, as the guide for the wheel flanges.

FIG. 1.—The broken line indicates the "Trackmen's Surface," while the surface of the rail under the driving wheels, the *Constrained Beam* in the General Depression. The cross-ties, ballast, and sub-grade are depressed decidedly under the specific deflections of the rails by the wheel contacts.

The positive bending moments under the wheels, and the negative constraining bending moments in the wheel spacing, with their respective fiber-strains, are indicated in the rails. The centers of gravity of the engine, locomotive, and tender are marked by a dot in their respective positions. Vertical scale of the General Depression is 24 times that of the locomotive.

The stiff rail section is the most conservative and useful member of the superstructure for this purpose, and advantage is taken of this fact in the construction of the American equipment, by distributing the total load on several wheels. The rails, cross-ties, and ballast, as illustrated by Fig. 1, are depressed from the trackmen's surface—represented by the broken line— $\frac{1}{4}$ to $\frac{3}{4}$ of an inch, to the loaded running surface in the general depression, by the wheel loads

Third: The entire section as a girder, to distribute the wheel-loads.

These are designated as bearing surface, guide, and girder, and illustrated by Fig. 2.

These three principles, embodied in a solid section, apply to limber or stiff rails, though the mechanical properties, as vertical stiffness and strength, will increase as the height and weight are augmented. See *Table No. 1*.

The numerous types of rail sections which

RAIL SECTIONS

have been designed, used, and sustained the service, since the installation of the railroads, are those only in which the bearing surface, guide, and girder have been fabricated in a solid piece.

The strap-iron rails on wooden or stone stringers, the compound rails of two or three pieces fastened together by rivets or bolts, all failed as engineering structures, from mechanical and metallurgical inefficiency, after short service, as the wheel-loads increased.

Fig. 2.—The Rail Section as an Engineering Structure of One Piece of Metal.

Physical Properties.—Sections of iron or steel have values as engineering structures according to their physical properties. The metal for the rail as the bearing surface, guide, and girder has therefore three requisite, dissimilar, but not inconsistent, functions to unite and serve by its physical properties.

First: The metal of the bearing surface under the rolling wheel contacts, in distributing its loads, resists deformation, shear and wear, principally by its mass hardness and cubic elasticity, and requires homogeneity, solidity, and malleability.

Second: The metal of the side of the head, as the guide for the passing wheel flange, resists abrasion best by its cell hardness and tenacity.

Third: The metal as the girder to distribute the wheel-loads, should provide for the bending moments, and consequent unit fibre strains, by less than one half of its elastic limits of linear elasticity.

The utility and durability of a rail section depend, therefore, upon the mechanical properties of its design, in combination with the physical properties of the material out of which it is fabricated.

Bearing Surface.—The functions of the section as a girder, for safety in distributing the wheel-loads, control the physical properties of the metal which may be provided for the bearing surface and guide. See Fig. 2.

The head of the rail must have sufficient width to form the bearing surface, to enable the metal, by its mass hardness, to receive and sustain the wheel-loads without rapid wear or decided permanent set as they roll over the rail. The metal in both the wheel and the bearing surface of the rail resists the intensity of pressure per square inch by its cubic elasticity, and to be efficient requires homogeneous solid metal.

The rails from the upper parts of the ingots often have an exterior layer of metal of normal chemical composition, but, owing to liquation in the fluid metal of the ingot, encloses a core of harder, more fusible steel, containing occluded gases affecting the homogeneity and solidity of the rail-head.

Such steel cannot sustain the heavy contact pressures of 100,000 pounds to 200,000 pounds or more per square inch, without flow or distortion, as its limits of cubic elasticity are reduced by the unsound metal.

Slight porosity in the steel, from entangled gas in the columnar structure one eighth of an inch under the bearing surface, develops into a defect under the traffic and a small piece becomes loosened and flakes from the inside upper corner. If the metal of the head of the rail is of coarse texture and unsound, it crushes for one eighth to one fourth of an inch under the wheel treads, and rapidly wears. See Figs. 8, 9, and 10.

Beneath the rolling wheel contacts the pressures are distributed both to the rail as the bearing surface and girder, by an area of steel from one tenth to one half of a square inch, which resists flow by support of the contiguous metal around and under the point of contact. While there is a slight compression of the metal, owing to its elasticity, it does not take a decided permanent set if solid, except by slight flow upon the extreme contour of the contact, to conform by its malleability to the average rolling wheel tread.

Stremmatograph tests on different sections show that, as the stiffness increases, the unit fibre stresses decrease, though the bending moments carried to make a smooth running track are augmented. This amplifies the wheel contact pressure intensity per square inch, imposing more work upon the metal in the bearing surface from the mechanical relations it sustains as part of the rail section in the more efficient girder or engineering structure. The quantity of metal in the bearing surface is limited in width of head, and reliance for effective service must be upon sound metal of good physical properties.

The axle loads, speed, and expended tractive effort produce two, three, or more times the burden by the passing wheels on the bearing surface of the present stiff rails than was borne by the former limber sections.

The bending moments carried by the light rails were only from 150,000 to 200,000 inch-pounds under the heaviest driving-wheel loads of the locomotives. On the $5\frac{1}{8}$ -inch 80-pound rails, under the present wheel-loads, they are from 250,000 to 400,000 inch-pounds, while on the stiff 6-inch rails they may be from 400,000 to 500,000 inch-pounds. See Table No. 1.

The physical properties of the best early steel rails were usually adequate for their conditions of service.

The metal in the section was of fine texture, solid, homogeneous, and in the bearing surface had malleability when its limits of cubic elasticity were surpassed, and ductility as a girder when its limits of linear elasticity were exceeded.

It is understood that, with the increase of the stiffness and strength of the section, the unit fibre strains would be decreased in the heavy and stiff rails.

RAIL SECTIONS

It is not known that, due to the looseness of the rails on the cross-ties, the latter in the ballast, and the depression of the roadbed to carry the wheel-loads, the bending moments augment with the stiffness of the rails. This reduces slightly the area of contact between the rail-head and the wheel-tread, and increases the intensity of the pressure per square inch, which has, and can be sustained by metal of sufficient physical properties.

The Guide. The Side of the Head for the Passing Wheel Flanges.—A track of which the alignment is nearly all tangent, the functions of the metal exercised principally will be in the bearing surface, and for the entire section as a girder to sustain, guide, and distribute the wheel-loads.

The fillet, in the throat of the flange of the wheels, by practically a rolling contact with the upper corner of the head, becomes sufficient to guide the passing trains without undue abrasion.

The three functions of the metal are required on curves, especially with combined gradients, to guide and change the direction of the trains, by the passing wheel flanges, which, by the pressure required, produces severe cutting abrasion on the inside rail-head, and on the opposite rail wear and flow of metal in the bearing surface by the wheel treads.

The loss of metal on the side of the head of the rail, as the "guide," by abrasion from the wheel flanges, is 3 to 10 times more rapid than from the same wheel treads in the bearing surface.

Rails of a quality of metal which on tangents will wear 6 to 10 years, on curves combined with heavy gradients may become flange-worn in 12 to 18 months.

Rails require width of head, tough, tenacious metal of fine texture, and hard as permissible, for the girder, to withstand long the abrasion of the wheel flanges.

The Entire Section as a Girder and Engineering Structure.—Provision for the mechanical properties of the section is made in the design, while as a metallurgical product the requisite physical qualities must be secured by the chemical composition, heat treatment, and method of manufacture, a series of difficult problems.

Safety is the first consideration, and the physical qualities must be confined to those for the bearing surface, guide, and girder, which will withstand the service of the rail in the track without fragility in the cold weather, which would render them unsafe.

The rail section as the girder, distributing its wheel-loads by longitudinal components of stress, must be made of a metal which permits, by its elasticity, the necessary flexures of the rails to carry the moving trains. The unit fibre strains in the limber steel rails were high, for those with elastic limits of only 30,000 to 35,000 pounds were limited to .001 of an inch extension per inch, before acquiring sets in service. Those in which the elastic limits were from 45,000 to 56,000 pounds only were capable of sustaining the unit fibre strains of the bending moments due to the wheel effects, without taking sets in the track.

Unit fibre stresses of 25,000 to 35,000 pounds under high-speed trains are to be expected in the rails, for they must sustain the wheel-loads

of the locomotives, the dynamic effects due to speed, and those due to the expended tractive effort.

The maximum unit fibre stresses in rails under daily trains are often two and three times higher than is considered permissible for bridge members. In rails, a stress under the wheels of either compression or tension lasts but a fraction of a second before reversal, while in bridge members a stress may continue for several seconds.

The sound metal in the heavy and stiff sections, which is enduring the service, has elastic limits of 55,000 to 60,000 pounds—nearly equal to the ultimate strength of the steel used for bridge members—and in addition has an elongation of 15 to 20 per cent in two-inch specimens.

The Barrow or other brands of early limber steel rails, in which the elastic limits ranged from 53,000 to 56,000 pounds per square inch, proved sufficient for the bearing surface, the guide, and the girder, for their limited mechanical properties and wheel-loads. The actions of the limber sections as engineering structures in the track are illustrated in Figs. Nos. 3 and 4, by a reproduction of a portion of one of the original diagrams by the Track Indicator, of the surface undulations of 10 rails. In Fig. 3 the joints are worn and low, and gave shocks to each passing wheel. The rails did not form a continuous girder for the strains in the general depression. The undulations as measured were 12 feet per mile.

Fig. 4 is from 10 new rails, poorly finished at the mills, and the cross-ties cut in the rail seats. Undulations, 8 feet per mile.

Fig. 5 is from 10 stiff 6-inch 100-pound rails upon the same roadbed as No. 4, the joints not being indicated: the undulations, 1 foot 9 inches to 2 feet per mile.

The stiff 5½-inch 80-pound rails do not show the joints until after years of service. Undulations, 2 feet and 9 inches per mile.

Figs. 6 to 11, inclusive, are photomicrographs of the structure of steel rails, each magnified 50 diameters.

Fig. 6 is from a Barrow rail 1868, and nearly all of the early steel rails had a similar structure. It is of fine texture, and has high limits of cubic elasticity. The steel was 0.40 in carbon and rolled from hammered ingots and blooms at a low temperature. The output was less than 200 tons per day and sold for \$120 in gold per ton.

The steel for the heavy sections should be of fine texture, sound, homogeneous, and tough, though more difficult to secure than in light sections.

The chemical composition, according to the weight of the section, ranges as follows: Carbon 0.50 to 0.65, manganese 0.90 to 1.20, silicon 0.10 to 0.20, phosphorus and sulphur, each not to exceed 0.07. In ores containing 0.10 in phosphorus, the carbon is reduced 10 to 15 points.

The ingots are bloomed in trains and rolled direct into rails at some mills, and in others the blooms are reheated for final rolling.

The structure for the finished rails is granular and often too coarse for durable service in the bearing surface and guide; and fragile as the girder.

RAIL SECTIONS

Attention is given to the rolling and finishing temperatures, to improve the structure.

Fig. 7 shows the structure of the first 6-inch 100-pound rails rolled 0.60 in carbon, and has rendered excellent service under the heavy wheel-loads.

Fig. 8 is from an 80-pound rail, 0.45 carbon

ported joints, has not been excelled for long, efficient service.

The number of cross-ties, 7 x 9 inches, 8 feet or 8 feet 6 inches long, range from 16, 18, to 20 per 33-foot rail. The ballast is of gravel or broken stone, 8 to 12 inches in depth, under the cross-ties in the main line tracks.

FIG. 3.—Surface undulations 4½ inch 65 lb. rails 1881. Joints low and worn.

FIG. 4.—Surface undulations, 4½ inch 65 lb. new rails 1888. Wavy finish and cross-ties cut in rail seats.

FIG. 5.—Surface undulations 6 inch 100 lb. rails 1892. Joints do not show their location.

and 0.10 in phosphorus—coarse, granular, and contains occluded gases.

Fig. 9, from the same rail, shows the structure as crushed for one fourth of an inch in depth in the bearing surface.

Fig. 10 is from a 100-pound rail of about the same chemical composition as No. 8, and crushed as a frog point after three months' service. The coarse structure has low limits of cubic elasticity and is fragile.

Fig. 11 is from an 80-pound rail which is rendering good service. The coarse structure of Figs. 8 to 10, inclusive, was due to the excessive heating and high phosphorus.

Rails in large sections have and can be made, by proper care in manufacture, which will be durable.

The 6-inch 100-pound rails of elastic limits of 60,000 pounds per square inch, laid on the "In-bound Main" at Grand Central Station, New York, in 1895, have carried over 300,000,000 tons, with only a loss in height of 3/32 of an inch in the bearing surface, exceeding the service of any light sections.

Rails at the mills are manufactured in two standards of length, 30 and 33 feet, with 10 per cent of shorts. They are laid in the track with either alternate or opposite joints, the former being general in America and the latter on the Continent. The joints may be suspended or supported, the former being common, though the latter prove to be the more efficient for long service, in making the rails a uniform, continuous girder under the passing trains. The types of joints as commercial products are numerous. The plain angle bar, with a thin web which can be punched out of steel of 55,000 to 60,000 pounds elastic limits, when in 36- or 40-inch lengths with 6 bolts, forming three-tie sup-

The periods of time which indicate the correlations between the sections as engineering structures and the driving-wheel loads, show that they have doubled practically on the stiff steel sections in the last 15 years.

The railroad companies have been quick to take advantage of such realities, by replacing their limber by 80-, 90-, and 100-pound stiff rails as the only and most economic method by which earnings could be saved, from an average freight rate of less than 1 cent per mile.

TABLE NO. 2. DRIVING-WHEEL LOADS IN RELATION TO SECTIONS OF RAILS.

| Section | Date | Pounds per wheel |
|------------------------|--------------|------------------|
| Strap iron..... | 1826 to 1833 | 1,700 to 4,000 |
| Iron tee..... | 1833 to 1863 | 7,000 to 10,000 |
| Light steel..... | 1863 to 1890 | 10,000 to 13,000 |
| Heavy and stiff steel. | 1890 to 1905 | 20,000 to 25,000 |

I was able to estimate and state the reduced undulations the stiff rails would record under my Track Indicator before they were rolled in 1883. They denoted higher standards than had been previously attained, and seemed improbable to officials.

The computed results for the Boston & Albany Railroad, with its curvature and heavy gradients, were, that the condition of track would be indicated between the 15th and 16th lines on the condensed diagrams.

The company commenced to lay their 95-pound rail in 1891, completed the line in 1897, and the average sum of the undulations per rail per mile, for the track inspection, was 15.42 lines on the condensed diagrams. I made the rails of 0.60 to 0.65 in carbon, the phosphorus not exceeding 0.06, and they were smoothly finished at the mills, to achieve definite effects.

The practical results since the transition from the limber to the stiff sections show that it has

RAIL SECTIONS

been imperative to introduce them, to carry the greater wheel-loads and check the rapid destruction of the cross-ties, which cost twice as much as the rails. The railroads have been enabled, without any other attention to the roadbed, to double practically the capacity of their tracks, by the increase of 60 to 100 per cent in the stiffness of their rails.

The important purpose in the construction of the superstructure of the track is to reduce and distribute the wheel-loads to such pressures, as the cross-ties and roadbed can sustain several thousand repetitions without decided permanent change, and the transition from the limber to the stiff rails has shown that this is the quickest engineering construction to load the foundation, for increased capacity.

Another method of distributing the loads and reducing their intensities to the ballast is by close wheel-spacing of the locomotives and cars—a feature of American practice.

The cross-ties under the limber sections were cut out in the rail seats by the intense pressures, while the ballast was overloaded to sustain 3,000 to 4,000 pounds per square foot. The stiff rails check the mechanical abrasion of the cross-ties, which can now be treated, and by that process add many years to their service.

The stiff and strong sections have enforced replacing the iron and steel bridges with those capable of carrying as heavy equipment as the rails.

The enlargement of the passenger locomotives—which had not been possible on the limber steel sections, owing to their weakness as girders—made rapid progress on the stiff rails, and in the Atlantic types now (1905) weigh 145 tons, while in the Pacific types 161 tons.

Equally useful to the railroads and community, beside the fast trains, has been the possibility of increasing the weight of the passenger, express, and mail trains to 500 or 600 tons, and run them upon schedules but little slower than those at high speeds and limited weight, the resistance being, on stiff rails at 55 miles, per hour about 11 and 10 pounds, respectively.

Freight locomotives of four, five, and in one type six, pairs of driving wheels, weight from 150 to 175 tons, are not severe on the tracks of stiff rails, when distributing their load and expended tractive effort under so many drivers. Freight trains of 2,000, 3,000, and 4,000 tons are in daily operation, compared to those of 500 or 600 tons on the limber rails.

The resistance of heavy trains is less per ton than those of smaller units. Freight cars of 60,000, 80,000, or 100,000 pounds capacity, with a spacing not exceeding 18 or 20 feet between the inside wheels of the trucks, make the general depression of the track continuous from the front pilot wheel to the rear wheel of the train. The foundation is loaded more favorably, and the train resistance decreased.

The greater capacity of freight cars has reduced the freight-train mileage, effecting an economy. In 1893 the freight-ton miles in the United States were 93,588,111,833, and the freight-train miles 508,719,506. In 1903 it was 173,221,278,993 ton-miles, and the freight-train miles only 526,312,433, an increase of 79,633,167,160 ton-miles, for less than 4 per cent more mileage.

This teaches the correlations between the

enlarged equipment on the stiff and strong rails.

The smoother track on the stiff rails reduces the train resistance by causing the centres of gravity of the wheels to roll forward with limited undulations, and this in turn the centres of gravity of the bodies of the locomotives and cars, one of the important factors in the recent progress of transportation. This fact of track construction and maintenance has not attracted academic discussion, but it does receive consideration and work as the railroad companies look to the physical condition of their tracks and the high standards of maintenance for economy and safety of operations. The expenditure for labor by the railroad companies of the United States in 1903 was \$139,000,000 to maintain the surface of the tracks. This sum represents annually nearly 1 per cent of the total cost of the investment and construction of the railroads.

The permanent way, composed of so many members safely but not rigidly connected, does not become a conservative system in which the strains incident to the passing locomotives and cars may be mathematically traced in their distribution in the rails, cross-ties, ballast, and subgrade, as in bridge members with rigid connections.

The International Railway Congress, at its second, third, fourth, and fifth sessions, had elaborate mathematical papers and discussions upon the subject based upon the consideration of static wheel-loads, then assuming what would take place under rolling loads.

The conclusions were not accepted in this country, in some respects, for they were not in accordance with the results of experience of distributed wheel-loads of American practice.

Prof. A. Flamache, chief engineer of the Belgian railways, considered all of the previous papers, and in the January Bulletin, 1904, of the International Railway Congress, Brussels, presented 30 pages of mathematical investigations, and concludes that the problem of what occurs in the rail under the rolling loads cannot be stated without more instrumental investigations for analysis.

Measurements of the unit fibre strains in the rails under moving trains have not been made abroad.

I ascertain the unit fibre strains in the rails under the moving locomotives and cars by means of my Stremmatograph, an instrument of precision, which segregates five inches in length of the base and records on a phosphor bronze slide the elongation and compression of the metal due to the passing wheel-loads.

The strains are measured under a special microscope, and from the modulus of elasticity of the steel the unit fibre stresses in pounds are ascertained. Then from the factors expressing the mechanical properties of the section the bending moments of the wheel effects are determined, as exhibited in Test No. 257, one of a series of precision, on stiff rails, to trace the distribution of the stresses under the moving locomotives. This seems to be for all the wheel contacts, as though distributed from the centre of gravity of the locomotive, in accordance with mechanics.

The test was repeated for the same train 30 December, and the total stresses compared within less than $\frac{1}{2}$ per cent. The average sum

RAIL SECTIONS

of the positive bending moments for both was 11.48 inch-pounds per pound of static load on 5½-inch 80-pound rail. Similar tests upon 6-inch 100-pound rails, at slower speeds, have been secured, of equal precision. The wheels must be perfect, and the engines performing the same work, for tests of precision. Engines with swing trucks do not give high degrees of exactness.

The tests also enable comparisons to be made between the types of locomotives in distributing their loads upon the rails.

At the same place, date, and speed as Test No. 257, a 10-wheel locomotive, weight 282,900 pounds, drawing the "Southwestern Limited," weight 910,000 pounds, the positive bending moment was 9.82 inch-pounds per pound of static load, for one rail. The closer wheel-spacing of the heavier, larger, and stronger locomotive, distributing its expended tractive effort under six instead of four drivers, was easier on the foundation or sub-grade than the eight-wheel type. This had been inferred from practice, and now confirmed by measurements.

NEW YORK CENTRAL & HUDSON RIVER RAILROAD.

P. H. Dudley's Stremmatograph Tests, 23 Dec. 1899.

No. 257. Track, No 1. Location, 6° curve 600 feet west of mile post No. 10. Rail 5½ inch, 80-pound. Moment of inertia, 28.5 4th-power inches. Cross ties. Length, 8 feet. Width, 9 inches. Thickness, 6 inches. Wood, Y. P. Weight, 155 pounds. No. 18 per 30 feet rail. Average weight of superstructure per yard, 449 pounds. Three-tie supported joints, 36-inch splice bars, stone ballast. Train No. 51, Empire State Express. Number of cars, 4. Weight, 430,000 pounds. Locomotive No. 870. Weight: trucks, 44,500 pounds; drivers, 86,500 pounds; tender, 89,000 pounds; total, 220,000 pounds. Speed, 42 miles per hour. Temperature, 40° F. The apparent mean unit fibre-stresses in the base of one rail were as follows in pounds:

| LOCOMOTIVE | | | Per wheel. | Per wheel base of | | | Per lb. of wheel base of | Wheel effects | |

RAIL SECTIONS

Test No. 257.—Reduction of sum of positive and negative bending moments to one pound of static load for one rail:

| | Inch-pounds |
|--|--------------|
| Engine, sum of positive bending moments.. | 821,245.00 |
| Engine, sum of P. B. M. per pound of static load | 12.65 |
| Engine, sum of negative bending moments.. | 125,234.00 |
| Engine, sum of N. B. M. per pound of static load | 1.92 |
| Tender, sum of positive bending moments.. | 438,911.00 |
| Tender, sum of P. B. M. per pound of static load | 9.75 |
| Tender, sum of negative bending moments.. | 63,279.00 |
| Tender, sum of N. B. M. per pound of static load | 1.40 |
| Locomotive, sum of positive bending moments | 1,260,156.00 |
| Locomotive, sum of P. B. M. per pound of static load | 11.46 |
| Locomotive, sum of negative bending moments | 188,513.00 |
| Locomotive, sum of wheel effects | 1,448,669.00 |
| Locomotive, sum of N. B. M. per pound of static load | 1.71 |
| First car, sum of positive bending moments. | 663,576.00 |
| First car, sum of P. B. M. per pound of static load | 12.52 |
| First car, sum of negative bending moments | 141,187.00 |
| First car, sum of N. B. M. per pound of static load | 2.66 |
| First car, sum of wheel effects | 804,763.00 |
| Weight of one-half of car, 53,000 pounds. | |

The Stremmatograph tests confirm that it is the combined wheel-loads and spacing which produce the specific deflections in the rails, and limit and control them, more than the flexible supports of the cross-ties. This fact is the fundamental principle of the American theory and practice of loading favorably the sub-grade through the distribution by their wheels of the total loads of the locomotives and cars. The stiff rails increased this efficiency to such an extent as to empower doubling the axle and total loads of the locomotives and cars, in the past 15 years, and at the same time secure and maintain smoother and better tracks than was possible on the lighter and limber rails.

The correlations of the stiff rail sections and the equipment are demonstrated and established by practice and analysis of tests, for under the wheel contacts in the general depression the positive bending moments are constrained by the negative bending moments, which check the deflections under the wheels, similar to the restrained beam of mechanics. To differentiate between the functions of the rail section and the "restrained beam" of mechanics, I designate the rail section on flexible supports under the rolling loads of the locomotive a constrained beam.

It is unique in the use of material or beams, that by a subdivision of the total load of the locomotives through the progressive wheel contacts, such favorable loading and distribution are made on the rail, and foundation; that the section by the function of its mechanical properties, in combination with its flexible supports and the sub-grade, is stiffened and strengthened—a reciprocal benefit.

This has been so advantageous with the American type of equipment that with all of the increase of axle and total loads, upon the stiff rails, reconstruction of the roadbeds has not been required. The wheel-loads carried are heavier than those abroad, and with the higher speed demonstrate that the essential running stability is secured between the equipment and permanent way, as well as upon roadbeds which

are considered more rigid. Baron Von Weber, director of the state railways of Saxony, in 1869, published a work on the stability of the permanent way, from his tests with engines of three pairs of drivers without trucks. His wheel-loads did not exceed 13,000 pounds, and he concludes, erroneously, that engines with two pairs of drivers would be preferable, and that the cross-tie supports should be replaced by a longitudinal system for heavier wheel-loads. His tests were valuable in many respects, though they did not lead to the consideration of all the elements of the running stability between the equipment and the permanent way, for we are now carrying driving-wheel loads twice as heavy as those in his investigations.

The running stability of the American railroads can be augmented by 9-foot treated cross-ties, screw spikes, and attention to the wheel-base of the engines.

The iron rail sections empowered the establishment of the railroads. The present development, efficiency, capacity, and prosperity has been in the period of the stiff steel rail sections, as engineering structures, and their correlations to equipment and operations of railroads.

P. H. DUDLEY, C. E., PH.D.,

New York Central & Hudson River Railroad.

Rails and Rail Shooting. Any birds belonging to the typical genera of the family *Rallidæ* are popularly called rails, probably in reference to their harsh rattling cries, but the name is more particularly applied to certain species, others being known as marsh hens, crakes, etc. The family is included in the order *Grallæ* or *Gruiformes*. The family is a large one composed of numerous species of moderately sized birds of generalized structure, found in most parts of the world. The body is compressed, the legs strong, the feet very large with long toes, which are lobately webbed in the coots, the wings and tail very short, the bill strong and variously shaped, but never greatly elongated nor provided with a sensitive tip; and the colors are usually obscure and sober. About 35 genera and 180 species of *Rallidæ* have been recognized, but authorities differ concerning the retention of some of the more aberrant forms within the family. Three subfamilies are represented in the North American fauna: the *Fulicina*, or coots, with lobate marginal webs on the toes and a horny frontal shield; the *Gallinulina*, or gallinules, with a frontal shield, simple toes, and usually richly colored plumage; and the *Rallina*, or typical rails, in which the family characteristics are best displayed, and there is no frontal shield nor any webbing on the toes.

Most of the rails are marsh-loving birds, their long toes admirably serving to support them on the soft mud, and their narrow compressed bodies facilitating movement among the stems of grasses and reeds. Owing to their skulking and largely nocturnal habits they are difficult to observe, and, except by gunners, their abundance is not generally known. They run well and to escape danger trust to their ability to slip quietly into a place of concealment. They seldom fly, and, owing to the shortness of the wings, only in a weak, uncertain manner, but nevertheless some of the species perform extensive migrations. In feeding they are chiefly carnivorous but never probe the mud for worms,

etc., in the fashion of snipes, nor strain it as do the ducks. The nest is usually a rude bulky platform of dried rushes, etc., slightly elevated above the wet ground and the numerous eggs are thickly spotted. The young are fully downy and are said not only to run but to swim well as soon as hatched.

Besides the corncrake (*Crex crex*), which occasionally wanders from Europe to our shores, 12 species of true rails occur within the boundaries of North America. They belong to two genera. The king rail (*Rallus elegans*) or fresh-water marsh-hen is our largest species, reaching a length of 18 inches and a wing expanse of two feet. It is known by the rich cinnamon and chestnut hues of the under parts and the strong streaking of the plumage above. This species is abundant in the fresh-water marshes of the eastern United States but, although occasionally seen in New England, is rather southerly. Except for its habitat and the character of its food, which consists largely of aquatic insects, leeches, and wild rice in season, the habits of the king rail closely resemble those of the next species. In the salt-water marshes from Connecticut southward along the Atlantic and Gulf coasts the king rail is replaced by the well known clapper rail or salt-water marsh-hen (*Rallus crepitans*), which is extremely abundant from New Jersey southward and is resident in the southern half of its range, but migratory northward. It inhabits the reed-covered marshes intersected by ditches and creeks which border so much of our coast within the beach line, and its presence is especially evident during the breeding season when the loud clattering cry is heard incessantly both by day and night. All kinds of snails, crustaceans, and worms inhabiting such regions constitute its food. The nest is a heap of dried reeds and grasses elevated just above the water by the side of a ditch, and usually concealed by an artful overarching of reeds. As many as a dozen, but more frequently about eight eggs, are laid; they are oval, of a cream or buff color and thickly blotched with brown and lavender tints. The clapper rail is slightly inferior to the king rail in size and is of a blended grayish color tone, rather than a streaked red. Closely related species are the *R. obsoletus* of California and *R. scottii* of Florida. The Virginia rail (*R. virginianus*) is about 9 or 10 inches long and in color a perfect miniature of the king rail. Unlike the latter it inhabits salt and tide-water as well as inland marshes, and is very widely distributed throughout temperate North America and southward. It is a regular migrant, in most of the Northern States and Canada, remaining from April to September to breed. Although generally common, they are best known by their nocturnal and diurnal cries. In nesting and other habits they resemble the clapper rails, but the eggs are of course much smaller. The Carolina or sora rail or crake and the yellow rail belong to the genus *Porzana*, which differs from *Rallus* in having the bill short and stout instead of long and slender. The former (*P. carolina*) is eight or nine inches long, brownish above and unspotted below, the latter (*P. noveboracensis*) is only about six inches long, with much yellow above and the breast spotted. Both appear to range widely in North America, but the former is everywhere

a far more abundant bird. The sora, also erroneously called ortolan, is the best known and during the migrations the most plentiful of the rails in all suitable reedy marshes along the shores of lakes and rivers, and it breeds in similar localities in the Middle States and northward. A third related species, the black rail (*P. jamaicensis*), is rarely taken. The North American rails are all marsh birds, but the European corn crake prefer the cultivated fields, and in New Zealand and other Southern islands many remarkable forms of field rails and some curious flightless and burrowing species are found.

Rail-shooting in the autumn, when they, and particularly the Carolina rail, congregate in immense numbers in the river swamps, has many followers; but it can hardly be called a sport, being nearly on a par with the annual slaughter of reed birds which occurs at the same time and places. The method is very simple: Each gunner has an assistant who poles him about in a flat-bottomed boat or skiff through the creeks and passages which everywhere intersect the swamps. Usually this is done at high tide, owing to the shallowness of the creeks at other times and because the rising water restricts the area on which the birds can run. Sometimes spaniels or other dogs are employed to drive the birds, but this is unnecessary, as they are easily seen as they run along the banks of the creeks or rise in short labored flight. Enormous numbers, often running into the hundreds, may be secured by a skilful shot who has mastered the problem of shooting from an unsteady boat. During the gunning season the sora feeds largely on the seeds of reeds and wild grains, becomes very fat, and is a truly delicate morsel. The other species are also sought but to a less extent. At times of unusually high tides great numbers of clapper rails are killed along the New Jersey coast as they huddle bewildered on little islands and masses of reeds in the flooded salt meadows. Immense numbers of the eggs of the same species are also gathered for food. Consult: Baird, Brewer, and Ridgway, 'North American Water Birds' (Boston, 1884), and Roosevelt, 'Game Water Birds' (New York, 1884).

Rails and Structural Shapes, Manufacture of. One of the most important branches of the iron and steel industry is the manufacture of rails. Up to about 1855, all rails were made of wrought iron. In England beginning about 1767, various forms of cast-iron and wrought-iron rails were employed, the first being a grooved rail for tramway purposes, which was subsequently developed into the regular railway by the use of cast-iron flanged rails. The first wrought-iron rail was patented in England by Birkenshaw, in 1820, and on account of its peculiar form was known as the "fish-belly" rail. It was the first to be rolled in continuous lengths embracing several spans, and was laid in cast-iron chairs spiked to stone blocks set at intervals of 3 feet. It weighed about 33 pounds per linear yard. Its manufacture by the rolling process, however, was quite difficult, and it was superseded by the "flat-foot" rail which combined a solid head with a flanged base and was laid by being fastened to timber sleepers or ties by spikes driven through the holes in the flange.

RAILS AND STRUCTURAL SHAPES

The flat-foot rail was followed by the bridge-rail, the double-headed rail, and the bull-headed rail. The last named, although involving a great waste of metal, owing to the excessive thickness of the web, is used exclusively in England, while in the United States and almost all foreign countries, the rail of the flanged T-section is universally employed. It was invented by Col. R. L. Stevens, in 1830, but the form in use in America is a modification suggested by the special committee appointed by the American Society of Civil Engineers, in 1893; while the form used in Europe is that invented by Sand-

FIG. 1.—Tramway rail.

berg. It is usually made in lengths of 30 feet, but rails as long as 60 feet are used to some extent. In weight, it varies from 25 to 100 pounds per linear yard, according to the amount of traffic, the speed of transportation, and the gradients and curves of the roads upon which it is used. About 1865, a few years following the discovery of the method of manufacturing Bessemer (q.v.) steel, rails of that material were experimentally rolled in the United States and soon began to supplant those of wrought iron. At the present time all rails are made of steel, and they have, probably, contributed more towards the rapid development of this country

FIG. 2.—Fish-belly rail. (a) Section. (b) Side view.

than any other single product of the steel industry. The raw materials consist of iron-ore, coke, and limestone, mixed in proportions as follows—ore 2 pounds, coke 1 pound, and limestone $1\frac{1}{2}$ pound. Two fundamental processes of manufacture are employed—the reduction of the ore in the blast furnaces and the conversion of the molten metal into steel in the converters, followed by the operations of the rolling mill. (See IRON AND STEEL.) The Bes-

semer process of conversion is generally employed on account of its rapidity as compared with the open-hearth process, taken in connection with its capability to produce a grade of metal of a quality sufficiently high to satisfy the general specifications for rails. In the manufacture of steel rails, the work of smelting the

FIG. 3.—Flat-foot rail.

iron in the blast furnaces is continued day and night, year in and year out, without intermission, but the converters and the rolling mills are generally shut down from 1.30 P.M., Saturdays, to 5 P.M., Sundays. During the intervening times, the product of the blast furnaces instead of being poured into the mixers (by which the

FIG. 4.—Bridge rail.

casts obtained from the different blast furnaces at varying temperatures and qualities, are reduced to a common temperature and quality), are run into the pig casting machine which consists of a series of parallel endless chains of molds arranged to pass in front of the pouring mouth of the ladle. The molds receive the

FIG. 5.—Double-headed rail.

metal at the lower end of the chain, and deliver the casts at the upper end of the chain, where they are loaded upon railway cars for shipment.

In the regular work, as soon as the ingot cast from the metal purified in the converters, is set, the mold is drawn from it by a hydraulic

FIG. 6.—Bull-headed rail.

stripper, and it is raised by an overhead electric crane and then lowered into the soaking pit, where it is brought to the proper temperature (white heat) for rolling. It is then taken to the blooming mill and passed through the blooms (rollers) seven times and reduced to a section varying in size according to the size of the desired rail. The section of the ordinary rail used on the railroads is $9\frac{1}{4}$ inches square, and

RAILS AND STRUCTURAL SHAPES

the ingot when rolled to that section attains a length of about 15 feet. It is then sheared into two or three lengths, as the case may be. These pieces called blooms after being heated

FIG. 7.—Flanged T section rail—80 lbs. per linear yard. Standard Am. Soc. Civil Engineers.

in the bloom furnaces are carried to the rail mill, which consists of three sets of rollers—the roughing rolls, the intermediate rolls, and the finishing rolls, through which the bloom is passed successively. Through the first set it is passed five times and reduced approximately to the section of the desired rail. It is then, without being re-heated, passed five times through the intermediate rolls and reduced more closely to the desired shape. If the rail is of the lighter variety, weighing from 50 to 70 pounds per linear yard, it is then passed through the last set of rolls and finished on a single

In the manufacture of “structural shapes” (a term which includes a great variety of angle-irons, T-irons, I-beams, Z-bars, eye-bars, channel-irons, and built-up posts, beams, and girders), used in the construction of modern buildings and bridges, the shapes are rolled from basic open-hearth steel of three grades—the rivet steel with an ultimate strength ranging from 48,000 to 58,000 pounds; the soft steel from 52,000 to 62,000 pounds; and the medium steel from 60,000 to 70,000 pounds. The elastic limit generally required is not less than one half of the ultimate strength, and the test pieces are required to be capable of being bent over through an angle of 180 degrees, without fracture. The raw materials consisting of ore and pig-iron, are melted down in the cupolas and are then run into the open-hearth tilting furnace, where an equal amount of cold scrap, in the form of steel junk, crop-ends, punchings, etc., from the construction shops, is added. The contents of this furnace, sometimes amounting to 75 tons, are poured into a hydraulic ladle crane, which is then swung over the casting pit, and the molten metal poured into the ingot

FIG. 8.—Rail passing through the intermediate rolls in the rail mill.

heat, with satisfactory results. But, if the rail is of the heavier class, ranging in weight from 80 to 100 pounds per linear yard, its tendency to retain heat longer, and therefore be passed through the finishing rolls at a temperature too high to give good results, is overcome by allowing it to remain upon a cooling table for an interval of time ranging from 45 to 90 seconds, and it is then passed through the finishing rolls at a lower temperature, thus giving a rail of a much better quality of metal, especially in the head of the rail. The rail is now sawed into the desired lengths, usually of 30 feet, and then passed through the cambering rolls, where it receives sufficient camber to prevent warping when it is being cooled. After being cooled off on the hot beds it is straightened, chipped, and filed, and is then ready for shipment as a finished product.

molds in the usual way through the bottom of the ladle. The ingots when set, are re-heated in the soaking pit, and then passed through the blooming mill and reduced to blooms and billets of any required size. They are then rolled to the desired shapes, sawed into the required lengths, and then cooled on the hot beds. From the hot beds they are passed through the straightening rolls, and after being cut into exact lengths, as required, they are ready for the construction shop.

In the production of finished bridge members, the shapes are carefully laid out by wooden templates, in which the precise positions of rivets, angles, gussets, etc., are marked. The operation of building up requires great care and accuracy. The shapes are sawed or sheared to exact length, and the sides and ends faced and planed down as required by the drawings.

RAILTON — RAILWAY ASSOCIATIONS

The small holes for bolts and rivets are punched by lighter forms of machinery driven by electric power; on the other hand, all pin-holes are first punched and then bored to exact diameter. In assembling, the rivet holes are properly registered, being reamed if necessary, and the separate parts bolted together, and finally riveted up by hydraulic, or pneumatic riveters. (See METAL-WORKING MACHINERY.)

In the manufacture of eye-bars, used in bridge construction, the tensile strength is limited to not more than 10,000 pounds below the test specimen of the grade of steel from which they are rolled. The eye-bar heads are formed by upsetting machines operated by hydraulic power, in which the heated end of the eye-bar is pressed to the desired circular form by the three-fold die of a hydraulic press, in a single operation. The head is then forged and punched at one heat, and then finished bored. Eye-bars are tested in a hydraulic testing machine capable of exerting a maximum pull of 700 tons. When an order of eye-bars is completed, one of the bars is pulled asunder in the machine. In general, they are required to show not less than 10 per cent elongation in the body of the bar, and they must break in the body and not in the eye.

W. MOREY, JR.,

Consulting Engineer, New York.

Rail'ton, Herbert, English artist: b. Pleasington, Lancashire, 21 Nov. 1857. He was educated at Mechlin, Belgium, and Ampleforth College, Yorkshire, and is very popular as an illustrator, among works which he has illustrated being the 'Jubilee Edition of Pickwick' (1887); 'Westminster Abbey' (1889).

Railway Associations. In the early days of railways their operation was but little more difficult to regulate than the service of the ordinary highway. The trains, few in number, were formed of connected stage coaches, or wagons, and were drawn sometimes by horses, sometimes by light locomotives. As traffic increased, trains multiplied, vehicles were enlarged, and the powerful engine of the present date, capable of hauling a train of a hundred modern freight cars, was eventually evolved. This great physical change has required a coincident development in rules and regulations, in order that the immense traffic of modern times, with its complicated movements over an interlaced system of roads, may be operated safely and efficiently. In this development each railway company formerly moved independently. The knowledge acquired by the officials of one company as the result of experiment and experience was unknown to the others, rarely communicated and sometimes jealously guarded. The problems presented eventually became so many and so intricate as to render the exchange of ideas and experience advantageous, if not imperative. This exchange has been mainly accomplished by means of railway associations. In no other line of business and in no other country has this co-operative work been developed so completely and so scientifically as among the railways of North America. It has been of incalculable value to the railway companies and to the traveling public.

There are more than 20 railway associations, national in their character, in North America; most of them are devoted to subjects connected

with operation and the others to questions concerning traffic. The term "operation" includes the supervision of the movement of trains, the maintenance of the superstructure, buildings and rolling stock and the exercise of discipline. The term "traffic" refers to business concerning rates and regulations affecting passengers, freight or other articles transported. Of the organizations devoted to "operation" the most important and influential is The American Railway Association, which had in 1903 as its members 218 railway companies, operating 212,849 miles of railway,—about 95 per cent of the entire railway mileage of the United States, Canada and Mexico. The history of The American Railway Association has been one of gradual development. Dating as far back at least as 1872, joint meetings of operating railway officials of superior grades were held semi-annually, with more or less regularity, having for their object the mutual arrangement of the schedules of through passenger trains between the east and the west and intermediate connections. Aside from such business, the first important co-operative work of this body, then called "The General Time Convention," was the approval of a detailed system of Standard Time proposed in April 1883, and its practical adoption in the United States and Canada on 18 Nov. 1883. Previous to that date every railway ran its trains by the local time of the city in which its headquarters were located, or some other arbitrary standard. There were over 50 standards in use, differing from each other by odd numbers of minutes. On the date named these were resolved into four standards based upon Greenwich meridian time, with differences of an even hour between them. Cities and towns throughout the country generally conformed their time to the new standards. Prior to 1883, the hand, lamp, whistle, color and bell cord signals in use upon the railway trains varied greatly. In some instances a motion of the hand or flag or the sound of the whistle would convey exactly opposite meanings to employees of different roads which used the same terminal stations for their trains. Bell cord and other signals were similarly at variance. A code of uniform train signals was adopted by the convention, taking effect 16 Nov. 1884. A similar organization of the operating officials of the railways between New York city and points in the South, called the "Southern Railway Time Convention," was formed on 24 Oct. 1877. This body accepted and approved the action of the General Time Convention with respect to standard time and uniform train signals, and co-operated in their adoption. On 14 April 1886, these two bodies were consolidated and a national organization formed, called "The General Time Convention." The name was changed to "The American Railway Association" in April 1891.

The object of the American Railway Association is the discussion and recommendation of methods for the management and operation of American railways. Its action is recommendatory, and not binding upon any member. Any common carrier operating an American steam railway is eligible to membership, subject to the approval of the executive committee. While any official of a member may be admitted to its sessions or serve on committees, the ranking official, who may be the president, vice-president,

RAILWAY ASSOCIATIONS

general manager, etc., casts the vote of the company or designates who shall cast it. Meetings are held semi-annually, in April and October. The work of the association is mainly accomplished through committees, and it is one of their functions to decide questions which arise in practice under the code of rules and to propose new rules to meet the great advances that are being made year by year in the methods of operation. Its technical standing committees are those on the subjects of train rules, car service and safety appliances. They examine into and report upon questions affecting the Standard Code of Train Rules, the movement of, distribution and accounting for cars, and the essential requisites of devices for safety appliances. Formerly each road had its own code of train rules. An employee, expert in the service of one road, found his knowledge useless on entering the service of another because the practice under the rules of the two was diametrically opposite. From the badly constructed and often discordant rules that preceded it, a scientifically arranged Standard Code of Train Rules was formulated, which each road could adopt and which most have adopted. This code has a glossary of technical terms and is divided into single-track rules for the movement of trains with or without the use of the telegraph; for movements by telegraphic train orders, with forms of orders; double-track rules; block signals and interlocking rules; for movements with the current of traffic on double track by means of block signals; and for movements against the current of traffic. In carrying merchandise from one part of the country to another the interchange use of the 1,700,000 freight cars belonging to the railway companies reaches enormous proportions. For many years the owner of the car was paid by the company using it at a rate based upon the miles it moved. Of recent times this was six tenths of a cent a mile, the account of the movement being kept by the company which paid for it. Complaints were frequent of long detentions of cars without compensation to their owners, causing delays affecting the transport of merchandise. Many attempts were made to bring about a change, but nothing practical was accomplished until The American Railway Association adopted a Code of Per Diem Rules in April 1902, and obtained the assents of the majority of the railways to a "Per Diem Agreement," taking effect on 1 July 1902. This provided for the payment of 20 cents a day for the interchange use of freight cars, with a penalty rate of an additional 80 cents per day for the detention of a car over 30 days upon one road. Provision was made for the arbitration of differences arising under the rules and for their interpretation. A code of car service rules governs ordinary practices connected with this interchange service, not related to the compensation paid as above referred to. The essential requisites for train heating, train lighting, automatic couplers, power brakes, for the installation of block and interlocking signal apparatus, etc., have been prescribed. The educational and physical qualifications for employees have been carefully considered. The Association prescribed the standard height of draw bars for freight cars, under the act of Congress approved 2 March 1902. The following

subjects have been at various times considered by special committees: the 24 o'clock system; the transmission of accurate time; uniform car mileage reports; general regulations for employees; standard wheel and track gauges; the metric system; railway statistics; standard box cars, and uniform cipher code. Uniform rules for the government of local car service (demurrage) associations were approved April 1898, and various recommendations of the Master Car Builders' Association have been submitted to and approved by The American Railway Association. The association is a member of the International Railway Congress, and sent delegates to its sessions in London in 1895 and Paris in 1900. It appointed an "American Section" to take charge of the arrangement for the seventh session of the Congress, to be held at Washington, D. C., in May 1905.

The Master Car Builders' Association is one of the oldest of these railway organizations. It was organized in 1867, and had 533 members in 1903. Its objects are the advancement of knowledge concerning the construction, repair and service of railroad cars, to bring about uniformity and interchangeability in their parts, and to adjust the mutual interests growing out of their interchange and repair. Its action is recommendatory, and not binding upon any of its members. A superintendent of the car department, master car builder, mechanical engineer, foreman of railroad car shop, joint car inspector or a representative of a car manufacturing company or other company owning over 1,000 cars, may become active members. Persons accredited by a railway company, and who have a practical knowledge of car construction, may become representative members. Such members, in addition to the vote of an active member, have one additional vote for each 1,000 cars owned by the company represented, upon all questions pertaining to the adoption of standards, etc. The membership includes many persons who are also members of the Master Mechanics' Association, and it is customary to hold the annual meetings of the two associations at the same place, one following the other. In the interchange of cars between railroad companies, questions of responsibility for repairs caused by accidents or by ordinary wear and tear are continually arising. In order to facilitate the settlement of such questions the Master Car Builders' Association has provided a code of rules governing the condition of and repairs to freight cars. Each company is required to give the same care to the cars of other companies in its possession, technically called "foreign cars," as to its own cars. Cars offered in exchange service must be accepted, unless found to be defective as specified in detail in the rules. The rules include instructions as to methods of making repairs and billing the expense to the owners, with schedules of charges for labor and materials. For the settlement of all disputes arising under the rules an arbitration committee is provided. This association brought about the selection of the type of automatic coupler, now in use upon the railway cars in North America. It has also adopted standards, both for the construction and use of cars, which have proved of great value. These standards, 23 in number, are fully illustrated and published with

RAILWAY ASSOCIATIONS

each volume of its proceedings, together with 12 additional charts containing diagrams of recommended practices.

The American Railway Master Mechanics' Association was founded in 1868, is incorporated, and had 755 members in 1903. Its objects are the advancement of knowledge concerning the principles of construction, repair and service of the rolling stock of the railways. It considers questions affecting such joint action as may be required to give the greatest efficiency to the equipment of railways. Those eligible to membership must have positions above the rank of general foreman, having charge of the design, construction or repair of railway rolling stock; general foremen, if their names are presented by their superior officers, and two representatives from each locomotive and car building works. Persons having knowledge of science or practical experience in matters pertaining to the construction of rolling stock, may become associate members. The subjects assigned to committees for 1903-4 were as follows: Ton mile statistics; coal consumption in locomotives; locomotive front ends; locomotive driving and truck axles and locomotive forgings; boiler designs; revision of standards, such as shrinkage allowances, specifications and tests for boiler tubes; air brakes and signal instruction; piston valves; electrical equipment of shops and power houses; automatic stokers; locomotive frames; cost of locomotive repair shop; and safety appliances for locomotive front ends. The proceedings of the association contain a technical illustrated history of the development of locomotives, shop engines and machinery, from the date of its organization. The association has established four scholarships at the Stevens Institute of Technology.

The International Association of Car Accountants and Car Service Officers was organized in 1876, has 180 members and meets annually. Its object is the improvement of and the establishment of uniform practice in methods of car accounting and car service. The compilation of the statistics of operation of each road requires that the movement of cars, both loaded and empty, shall be accurately recorded. The interchange use of the 1,700,000 freight cars in service between the railway companies involves an immense amount of detail work in keeping and settling the accounts. Since the value of a freight car as a vehicle of transportation based upon its average earnings is between \$2 and \$3 a day, the importance of the figures involved in this accounting is self-evident. This branch of the service is part of the operating and not of the general accounting department. An official publication called the 'Railway Equipment Register,' contains lists of the cars of the several companies, giving in detail their numbers, dimensions, capacity and kind, such as box, flat, coal, etc., and other information essential to operating officials in regulating car movements and in car accounting under the rules of the association.

The Railway Transportation Association has for its object the development and solution of problems affecting transportation in the mutual interest of railway companies. It was organized in 1899, meets semi-annually and has 58 members, representing the owners of over 1,000,000 freight

cars. Aside from general transportation topics, it considers such subjects as the responsibility for the transfer of freight interchanged; the handling of high class freight trains; the limits of class and size of freight cars; the interchange and distribution of equipment; tonnage; the loading of freight cars to their full capacity, etc. As the object of this association and that of the Car Accountants' Association somewhat overlap, and many officials are members of both bodies, a consolidation into one of enlarged scope, to include the objects of both, is probable.

The Association of Railway Telegraph Superintendents was organized in 1882, has 112 members, and meets annually. Its object is the improvement of the telegraph service. Its membership consists of persons who are connected with the telegraph, telephone, electric light, electric power or electric signal department of any railroad company. It has committees on the following subjects: telegraph cipher code; typewriter in railway telegraph service; and on composite circuits. The duties of telegraph superintendents cover the maintenance of the telegraph lines, as well as the supervision of the operators in the service.

The Train Dispatchers' Association of America has for its object the consideration of the best method of moving trains by telegraph, the establishment of a bureau of information, and the advancement of train dispatchers in efficiency in the performance of their duties. It was organized in 1888, is incorporated, has 868 members, and meets annually. The movement of trains by telegraphic orders, as commonly practised in North America, is unknown in Europe. The details of such movements are directed by designated telegraph operators, called train dispatchers, under the direction of a chief train dispatcher, attached to the staff of the superintendent, by whose authority the orders are given.

Associations of Surgeons.—It is customary for railway companies to retain in their service the services of experienced surgeons located at points on their lines, who are expected to be immediately available in case of accident to employees or passengers, some one of them being often designated as Chief Surgeon. In addition to this duty, hygienic questions are submitted to them, and their services are sometimes employed in the examination of men seeking to enter railway service for color blindness or other physical disabilities. They have two organizations, the International Association of Railway Surgeons, with 670 members, formed in 1888, and the American Academy of Railway Surgeons, with 141 members, formed in 1894, and their consolidation is probable. Their objects are the development and improvement of railway surgery, especially by the study and investigation of clinical, medico-legal and sanitary subjects relating thereto.

National Association of Car Service Managers.—For the purpose of supervising the movements of freight cars especially at terminal and junction points, so as to prevent their undue detention in loading or unloading, Car Service Associations, composed of the railway companies centring or connecting at such points have been organized under rules approved by the American Railway Association. Each local organization is in charge of an official called the

RAILWAY ASSOCIATIONS

car service manager. Thirty-nine of these officials organized a national association in 1890 for the purpose of obtaining a general exchange of views as to the best methods of conducting the business and to secure harmony of action.

The Railway Signal Association was organized in 1897, has 355 members, and holds five sessions per year. Its object is the advancement of knowledge concerning the design, construction, maintenance and operation of railway signaling appliances, by discussion, investigation, and reports of experience, for the purpose of systematizing and improving signaling practice. Its membership consists of those persons who are connected with the designing, construction, maintenance or operation of signals. The signal department of railways is one of the youngest and most rapidly developing branches of the service. The subjects considered by its committees are: circuits for automatic block signal systems for steam and electric railroads; for manual block signal systems; for interlocked signals; and for drawbridges; on what shall be considered cost in estimates for installation and records of maintenance; on the use of copper or iron for pole lines; on standards, definitions, nomenclature, office records and accounts.

The American Railway Engineering and Maintenance of Way Association was organized in 1899, has 425 members, and meets annually. Any civil, mechanical or electrical engineer, who has had five years' experience in the location, construction or maintenance of railways, or an official responsible for the maintenance of way, from general manager to division engineer, or whatever may be his title, is eligible for membership. Its working committees are assigned to the following subjects: graduation; ballasting; ties; rail; track; buildings; bridges and trestles; masonry; signs, fences, crossings and cattle guards; signaling and interlocking plants; reports, records and accounts; uniform rules, organization, titles, code, etc.; water service; yards and terminals. One of its purposes is the establishment and maintenance of a library of information concerning maintenance of way matters.

Other national associations of railway officials and employees of the operating department organized for the improvement of the service comprise: Superintendents of bridges and buildings; master boiler makers; master car and locomotive painters; railway air-brake men; master blacksmiths; roadmasters; traveling engineers, dining-car superintendents, and local freight agents. There are also numerous local organizations, such as the Chicago Association of General Superintendents, the Central Association of General Railway Officials, with divisions in Cincinnati, Columbus, Indianapolis, Kansas City, Peoria, Saint Louis and Toledo; the Central and Western, and the Eastern Association of Car Service Officers; Eastern Maintenance of Way Association; Canadian Roadmasters' Association; Buffalo Railroad Association. Railway Clubs, organized for the discussion of technical railway questions, are located at Atlanta, Boston, Buffalo, Chicago, Colorado Springs, Denver, Des Moines, Ia., Macon, Ga., Montreal, New York, Pittsburg, Richmond, Va., Saint Paul, Saint Louis and San Francisco.

The American Association of General Passenger and Ticket Agents, organized 13 March 1855, is the oldest railway organization in America. The ranking officer of the passenger department of each railway corporation and transportation line is eligible to membership. It had 174 members in 1904 and meets annually to discuss matters of general interest to the passenger department. Through this association the American system of interline coupon tickets was introduced, by which passengers are able to purchase tickets from each principal point to all other principal points on the continent. This system has been perfected in North America as in no other country in the world. The association has also prepared standard forms for railroad tickets, and has an organization for the better protection of tickets against alteration, forgery, etc. Formerly the meetings were held to arrange the rates of fares over through routes; but this duty is now performed by local organizations composed of lines operating in separate districts, namely, New England Passenger Association, Trunk Line Passenger Association, Central Passenger Committee, Western Passenger Committee, Trans-Continental Passenger Committee, Southeastern Passenger Committee, etc.

The American Association of Traveling Passenger Agents, organized 17 April 1872, has 867 members and meets annually. Its membership consists of authorized representatives of railway and steam navigation lines, who travel for the purpose of soliciting passenger traffic. Its objects are to suggest such reforms in the railway passenger service as experience may teach to be beneficial to both members and the interests which they represent.

The American Association of General Baggage Agents, organized February 1882, is composed of the general baggage agents of the several transportation lines. It had 67 members in 1904, and meets annually to discuss questions connected with the transportation of baggage, with the view of securing the greatest efficiency, as well as uniformity of practice, in allowance for weight carried free, methods of tracing baggage lost in transit, facilitating its prompt handling, etc.

The Association of American Railway Accounting Officers, organized in 1888, consists of the chiefs and assistants of the various departments of railway accounts. It had 378 members in 1904, representing 223 companies, and meets annually. It is general in its character, rather than a traffic organization. Its objects are the better organization and conduct of the accounts of transportation lines; to aid in securing more perfect means of determining balances between the companies and greater definiteness and promptness in paying the same; greater uniformity in the method of adjusting joint accounts; more equitable plans for settling claims between carriers; greater certainty and promptness in collecting freight charges at competing points; better means of adjusting balances at junctions where freight is rebilled; to obtain greater uniformity, wherever practicable, in the governmental reports required of railroads; and the more general systematization of railway accounts.

The Association of Railway Claim Agents was organized in 1890, has 346 members, and meets annually. It consists of the officers and their assistants who have charge of the investigation of claims for damages (other than freight), their adjustment or defense. Its object is the interchange of experience and the discussion of any subject of interest to railways in the department represented by its membership.

The Freight Claim Association was organized March 1892 by the consolidation of local associations for kindred objects, which had been in existence since 1887. Its membership consists of the general freight or claim agents or other authorized representatives of the general freight or freight claim departments of railroads, transportation lines or companies, including 237 members, representing 181,000 miles of railway. Object: the prompt and equitable settlement of freight claims with claimants and between carriers. This association has formulated a code of rules for the settlement of claims of every variety arising for loss or damage to freight in the handling of traffic. It has an Arbitration Committee which acts as a court for the interpretation of the rules as applied to such questions in dispute as may be referred to it by the parties in interest. W. F. ALLEN.

Railway Bridge Designs. See BRIDGE DESIGNS, RAILWAY.

Railway Car Braking.—To ascertain the time when the question of braking first came into prominence we need go no further than the period when highways became sufficiently well made and maintained as to admit of a heavy vehicle being drawn over them at comparatively high speed. Country roads everywhere as late as 1725 were in a most deplorable condition, being narrow and full of ruts and stones. During the middle of the 18th century there was considerable agitation for better roads, which seemed to have a beneficial effect, since during the latter part of this century the first mail coaches, or "Diligences," were placed upon the roads between London and various cities of Great Britain.

It is a noticeable fact that, with, all kinds of conveyances, the question of braking has increased in importance as the demand for higher speeds increased. During the century from 1770 to 1870 there were granted in England nearly 200 patents for various kinds of braking appliances for common road vehicles; of these 46 were applied to the periphery of the wheel; 28 on the nave, 27 were actuated by the movement of horses, 21 were applied to fly or brake wheels, 8 were applied to the axle, 10 were actuated by a spring, 4 were automatic, 3 electromagnetic, 3 pneumatic, 4 relying on momentum, and 3 accumulated power for subsequent propulsion, etc. In America there had been nearly as many such patents, 21 of which were for automatic designs.

In connection with common road vehicles it is noted that the first devices adopted are those which have formed the basis of almost all brake appliances which have since been employed for the same kind of vehicle. The

early stage coaches and even the later mail coaches were provided with an iron shoe which slips under the wheel and is chained to the fore part of the coach, so as to drag both shoe and wheel along over the surface of the ground. This method of braking was one of the first devices adopted, and is used extensively to-day. The old arrangements of two brake blocks and a beam with suitable levers connecting each to the driver was also early introduced, and all kinds of developments from this arrangement are seen to-day on various kinds of vehicles.

Many primitive forms of brakes were applied to such railroads as existed, but the speeds employed on these roads were generally low and the cars small enough to be drawn by draught animals, and the question was not a particularly serious one until the advent of the steam locomotive. The great revolution which the knowledge of the power and use of steam has brought about was well under way during the first part of the 19th century. During the first 70 years of the century about 650 patents were granted in England for various kinds of brakes for railroad service. In 1833, Stevenson patented his steam brake, consisting simply of a small cylinder containing a piston, the rod of which connected through a system of levers to a cam brake. The first pneumatic brake was a vacuum brake, patented by James Nasmyth and Charles May in 1844. In 1848 Samuel C. Lister patented an air brake, having an axle-driven pump and suitable reservoir to be placed on the "guard's carriage," and suitable cylinder, pipe and connections on the various cars to constitute a straight-air equipment.

Many interesting and ingenious contrivances were suggested and patents obtained for same in the United States. The "Cramer" brake, which was brought into use in 1853, consisted of a large spiral spring attached to the brake staff at the end of the car, and which was wound up by the brakeman immediately after leaving a station. The "Loughridge chain brake," which came into use in 1855, consisted of a system of rods and chains continuously connected throughout the train. These types were the results of much research. There were many other forms of brake which attained a certain degree of prominence, and were more or less successfully operated upon different roads throughout the country.

In 1869, the Westinghouse non-automatic air brake, which has since generally been designated as the "straight air" brake, was brought out. It consisted of a simple steam-actuated air pump placed upon the side of the engine, and a reservoir in which the compressed air could be stored. A pipe line from the reservoir was carried throughout the length of the train, connection between vehicles being made by means of hose and couplings. Each vehicle was provided with a simple cast-iron cylinder, the piston rod of which was connected to the brake rigging in such a way that when the air was admitted to the cylinder the piston was forced out and the brakes thereby applied. In the engineer's cab

RAILWAY CAR CLEANING

there was placed in the pipe line a three-way cock, by means of which compressed air could be admitted to the train pipe, and thus to the cylinders on each car; or the air already in the cylinders and train pipe could be discharged to the atmosphere, thus releasing the brakes.

This was the simplest and most efficient brake that had been introduced up to that time, and was largely adopted by American railways; but while all that could be desired for single vehicles, the danger incident to the entire loss of braking power when most needed, due to the bursting of hose under pressure, the parting of the train or other rupture of the brake system, led to the invention of the automatic brake. The first form of this brake was introduced in 1872, and is now generally referred to as the "plain automatic." The essential difference between this brake and the "straight-air" type, which it superseded, consisted in the installation of supplementary or auxiliary reservoirs for the storage of compressed air on the cars in addition to the main reservoir on the locomotive, so that each vehicle carried its own supply, and the employment of a most ingenious valve mechanism, by means of which the application of the brake was caused by the reduction of air pressure in the train pipe, whether such reduction was made intentionally or as the result of accident.

The original three-way cock in the engineer's cab has been lately replaced by a more elaborate valve known as an engineer's brake valve. The necessity for this substitution was due to the fact that in applying the brakes the reduction of pressure in the trainpipe had to be more carefully made than was practicable with an ordinary three-waycock. The brake valve was arranged so that in releasing the brakes, air was allowed to flow from the main reservoir on the engine into the trainpipe and auxiliary reservoirs. The engineer by moving the handle to the application position connected the trainpipe to the atmosphere through very carefully graduated openings, and the pressure gauge connected to the trainpipe showed how much reduction was made, and indicated, therefore, the amount of air that would flow from the auxiliary reservoirs into the brake cylinders.

The immense advantage to railway companies along the line of higher speed, greater safety and pronounced economy in the substitution of a reliable automatic power brake under the control of the engineer for the old hand brake was soon recognized, and the work of making this change proceeded rapidly throughout the entire country. Naturally enough, the new conditions encountered brought to light new problems, the solution of which enlisted the best efforts of railway officials and brake manufacturers alike. In many instances it was found that the only possible way to determine the questions involved with any degree of satisfaction was by means of practical tests made under conditions found in actual service.

Very recently, the greatly increased speed of all classes of passenger service, coupled with the demonstration that in order to approach

a uniform rate of retardation it was necessary to have a much higher brake-shoe pressure for high speeds than for low, rendered imperative the "high-speed brake." This apparatus consists of the quick-action automatic brake, with the addition of an automatic reducing valve connected to the brake cylinder. The normal train pipe and auxiliary reservoir pressures are raised from 70 pounds (the ordinary quick-action pressure) to 110 pounds. The reducing valve is arranged so that in service applications the brake cylinder pressure cannot exceed 60 pounds, but in emergency application the initial cylinder pressure becomes nearly 90 pounds, which is gradually reduced as the speed decreases, until 60 pounds is reached, which pressure is retained until released by the engineer. This high-speed brake has reduced the distance within which a train can be stopped by at least 30 per cent. See RAILROAD SYSTEMS. EDWARD S. FARROW,

Consulting Railroad and Mining Engineer.

Railway Car Cleaning. From the early days of railroading until the present time constant attention has been given to the requirements of sanitation of passenger cars, and how best to insure cleanliness has been a problem with no easy solution. The old method of car cleaning with a whisk here and a dash there with a broom or duster, was not only unsanitary, but unsatisfactory for the reason that it had the effect largely of removing dust and dirt from one section, and depositing it elsewhere; but under the latest and most highly approved method, which is termed the "Vacuum Sweeping System," the dirt and dust are drawn from the car by suction through a pipe.

Prominent railroads have recently erected immense vacuum plants in their car yards, and for distances of several thousand feet have laid pipes varying from two to five inches in diameter. At short intervals this pipe is tapped and from these cocks is run the flexible hose, which may be taken in the car, either by door or window. At the foot of the hose is a metal pipe with a flat triangular end, along the base of which is an opening, and through which the dust and dirt are drawn by the vacuum or "drawing-in machine" located a distance away. The operator runs the slot opening over the cushions, carpets, curtains, woodwork, etc., and without any commotion or dust raising, every loose particle or germ is whisked away, everything being left clean and wholesome. The dust thus removed, before reaching the "drawing-in machine," passes through two dust separators, the first of which clears the air of 90 per cent of the grit, dust and germs; the second separator or cylinder draws the air through water in which corrosive sublimate is used, and completes perfectly the purification. Railroad managers have for a long time felt the necessity for a more sanitary method of car cleaning, and the vacuum system, while reducing disease liabilities to a minimum, at the same time reduces the cost of cleaning and time consumed. Two cars can be thoroughly cleaned under the new system at the same expense of time and money as was formerly consumed in cleaning one.

The only valid objection to the vacuum system is the cutting out the pile of the plush very much

more rapidly than the process of hand beating, there being more or less sand in the cars. In Jersey City, where perhaps the largest number of cars are cleaned, the other methods in vogue are essentially as follows: (1) The carpets are removed by rolling them in bundles, and then taking to the cleaning shed. (2) The seats, cushions, pillows, mattresses, and blankets are removed to a shed alongside the car, where they are beaten, dusted, and aired. (3) Men go through the car and dust all portions, including the upper berths, with feather dusters, immediately after which the upper berths are closed. (4) The charwomen wash the woodwork and glass with lukewarm water and castile soap. The rugs, particularly those of the smoking compartments, are, if badly soiled, washed with soap and water and then dried. The cars cleaned in Washington and Jersey City are treated in this way every other trip, being only swept at the end of each run.

This vacuum cleaning process has of late been successfully applied in the New York Subway, where it has been demonstrated that a suitable car fitted with a plant can clean one of the stations in less than half an hour, and that while running between stations it can take up the loose dirt from the roadbed and dump it in the yard at the terminal after all the stations have been swept.

Railway Consolidation. The consolidation—or as the English say, the amalgamation—of railways consists either (a) in uniting connecting lines into one continuous line, or (b) in uniting parallel or competing lines into a system. Railways in the United States were originally built for the most part in short, disconnected lines—little stretches of road from A town to B town. Construction had progressed only a little before the desirability of connection between these lines became obvious. And almost at once such connection began to be arranged, so that, in the progress of our railway building and some time prior to about 1870, a great number of these little lines in every part of the country had been amalgamated, with the result of developing our great trunk line systems. Before we had entered upon the last quarter of the 19th century, it had come to pass, speaking generally, as a result of this tendency to unite connecting lines, that very much the greater and more important part of our railway system consisted of long lines of road under a single management or control, made up, especially in the older parts of the country, of a less or greater number of formerly disconnected and independent local lines, which had been one after the other taken over and incorporated into the greater continuous line or system. Almost all the valuable and well located local lines had, 30 years or more ago, thus been absorbed into larger and less local combinations. Such consolidation, working only benefit to the public and demonstrating its usefulness as it went along, provoked only a small amount of opposition, and these amalgamations of connecting lines usually secured legal sanction, whenever necessary, without the protest of the politicians. But about 1870—now a full generation ago—a tendency in the direction of the consolidation of parallel and competing lines developed. What had long been known in Europe

to be the true law of railway construction, and the sound basis upon which railways must ultimately come to exist and be operated in every country where there is enough wealth and commercial activity to make them successful—namely a division of territory and the practical elimination of competition between parallel lines in the same territory—began to assert itself and to be felt to be applicable here: and directly we entered upon a period of consolidation, not now of connecting but of competing lines; and, summing up the whole matter in a single sentence, that process of amalgamation, having now gone on in this country for nearly 40 years, it results that we are now at the end substantially, of the second stage of railway combination.

First, we built isolated and disconnected local lines; second, we united these connecting lines—whenever they did connect—into continuous lines; and third, we divided up the territory between theretofore competing lines, by gradually amalgamating either the ownership or the control of such lines in a defined territory, thus securing little by little to a single interest, a territorial monopoly of the carrying services of the locality. This process carried out to its logical conclusion roughly divides the whole country into railway territories of greater or less extent, within each of which one single railway system is paramount or absolutely controlling. This readjustment of ownership and control between the greater railway companies of the country goes steadily on. In some sections of the country it seems to have been fully and finally accomplished; in other sections it is in progress; and only where the game isn't worth the candle or where the work has been done, is there an absence of activity in this direction, the tendency so to consolidate, first connecting and then competing lines, has been universal and inevitable, and such consolidation is in the one case an accomplished fact and in the other an irresistible evolution. Very little effort was made to prevent the earlier consolidations, that of merely connecting lines. It is now well understood that such efforts, if they had been made, would have failed, and it is now not questioned that such consolidations have been beneficial both to the public and the railways. On the other hand a very great deal of effort has been made by courts and statutes to prevent and hinder the second form of consolidation, that of competing or parallel lines. These efforts have also for the most part failed, and it is now coming more and more to be believed that they will ultimately wholly fail to prevent what seems to be the inevitable in railway development. Moreover, in the case of the amalgamation of connecting lines, the mischiefs which have been apprehended have generally not been realized; so that now not only most practical railway men, but many students of the railway problem believe that in the outcome the balance of benefit both to the carrier and to the public will be also found on the side of territorial division between competing lines.

The history of railway construction and combination throughout the world seems to indicate *first* that the consolidation of competing lines is inevitable; *second*, that efforts by legislation or litigation to prevent it always fail:

RAILWAY CONSOLIDATION

and *third*, that such consolidations benefit both the public and the railways. The facts and figures concerning these consolidations in the United States are detailed elsewhere in this work, but the economic questions involved are still open ones with us. Elsewhere throughout the world these questions seem to be settled. Thus in England, where the railway problem has in many of its features been strikingly like our own, the question is now quite at rest. In France the question never really arose, and elsewhere in Europe it has been decided everywhere in favor of amalgamation and against the continuation of competition between lines serving the same territory. (The writer's argument in the Supreme Court of the United States, October Term, 1903, upon the appeal of *The Northern Securities Company et al v. the United States*.)

England.—In February 1872, a Select Joint Committee on Railway Companies Amalgamation was appointed by the two Houses of the English Parliament to investigate and report back the condition of the railways of Great Britain, particularly in respect of the consolidation of lines and the division of territory among the greater companies. Mr. Chichester Fortescue, in moving the appointment of the Select Committee in the House of Commons, on 23 Feb. 1872, said that "twenty years ago a Committee had reported against the system of amalgamation, but since that committee reported amalgamation had gone on as merrily as before—the fact being that 5,000 miles of railway had been added to the greater railways since that time."

This committee called a great number of witnesses and went fully into the details of the matter throughout the British Islands, and on 2 Aug. 1872, presented a voluminous report, from which it appeared that by the end of the year 1843, 71 separate and independent lines had been constructed, averaging about 30 miles each in length. During the following year the average mileage per independent line was reduced one half, so that by the end of the year 1844 the average was only about 15 miles. Between 1844 and 1847, 637 separate companies had been chartered, with a total authorized length of about 9,400 miles of line. Eleven proposals, for example, were made to Parliament for lines of railway through a single narrow valley, where but one line was possible. This called so loudly for relief that consolidation began about 1847, and so proceeded, by the gradual absorption of the smaller lines by the larger systems, and by a consequent division of territory between the consolidated companies, that by 1872 it had come to pass that the railway business of the Kingdom was substantially performed by no more than about six of these great amalgamated companies. The first English railway charters contained provisions intended to prevent competition both between the lines themselves and between them and the canals, especially in freight traffic. George Stephenson, the father of English railways, seems to have appreciated clearly the mischief to be avoided in the matter of competition, even at that early day, and he, therefore, set himself to the task of getting the railway system in that country started right in this particular. His view on this subject was summed up in his

much-quoted saying that "where combination is possible, competition is impossible."

In 1836, a Mr. Morrison, M. P., from Inverness, made a remarkable speech in Parliament, in the course of a discussion of the then English railway situation, in which he pointed out with uttermost clearness that a railway must in the nature of things be a monopoly; that competing roads will inevitably combine; that parallel lines are sheer waste of capital, and that fixed maximum rates are useless. This utterance is the more remarkable because it stated clearly, at the outset of railway building and before there was any basis of fact and experience upon which to found such generalization, the ultimate principles which long experience has since demonstrated to be sound.

Thus it is seen that the English railways started right, but that they soon got wrong, and for the first 30 years and more, blunders in plenty were made in futile endeavors to construct and operate railways on the principle of inter-competition. Uncounted treasure was wasted in these attempts, and absolutely nothing but experience was gained by it. By 1872 competition had been substantially eliminated through the operation of natural laws and in spite of hostile legislation and litigation. It was said in Parliament, in the debates over the appointment of the Select Committee in 1872, that there was not at that time a single competitive rate existing in the Kingdom. With the legislation of 1873 the general railway situation in England was fixed and determined, and the agitation for competition ended. The railways ceased to be bugbears, and fears of mischief to the public from the growth of railway influence and power gave place to intelligent criticism of railway methods and to a public-spirited determination to get good service at fair rates while giving the companies a free hand to manage their finances in their own way. Thus, after nearly 40 years of experiment, agitation and disturbances, the English people came back about 1872 to their point of commencement. Mr. Adams, in his 'Railroads and Railroad Questions,' says that then England "settled down on the doctrine of *laissez faire*"; and President Hadley, in his 'Railroad Transportation,' says "It might better be said that it has settled down on the policy of specific laws for specific troubles." By about 1872, as we thus see, the problem was solved by the operation of immutable economic laws, and the decision against competition between lines made beyond all possibility of reversion. To make a summary statement it appears that in 1847 there were about 5,000 miles of railway in England, owned and operated by several hundred independent and competing companies; 25 years later there were 13,000 miles of railway, owned and operated by 12 partly competing companies; now there are a little over 15,000 miles, owned and operated by about six non-competing companies.

The history of some of the greater English companies taken a little in detail illustrates the situation. The London & North-Western Railway was first opened for traffic in 1837, about a month after the accession of Queen Victoria. In 1846, it consisted of a main line from London to Birmingham, with some insignificant branches. In 1852, a writer on the position of the company

RAILWAY CONSOLIDATION

complains that it "fell a few years back into the error generally committed by railway companies of amalgamation with numerous other railway companies. From being a line from London to Birmingham, 112½ miles, it has become a line or lines of 539½ miles long—five times its original length." Since that time it has increased its mileage nearly four-fold, and has merged into its system the Chester and Holyhead lines on the west and the Lancashire and Carlisle on the north, besides numerous smaller undertakings too numerous to mention. The Great Western Railway has been absorbing smaller independent lines in its territory for many years, and altogether considerably more than 100 have been so absorbed within the last 40 years. Since 1896 it has taken over about 20 such lines, adding thereby 260 miles to its system. Of its total capital expenditure from 1892 to 1901, amounting to about 15½ millions sterling, nearly 5 millions represented amalgamations. The North-Eastern Railway is a consolidation of various small lines which has resulted in a vast network of railway in the northeast of England without a single intruder in the territory in the shape of a competitor. The report of the Select Committee on Railway Amalgamation in 1872 contained the following reference to this line:

The case of the North-Eastern is a striking illustration. That railway or system of railways is composed of 37 lines, several of which formerly competed with each other. Before their amalgamation they had, generally speaking, high rates and fares, and low dividends. The system is now the most complete monopoly in the United Kingdom; from the Tyne to the Humber with one local exception, it has the county to itself, and it has the lowest fares, and the highest dividend of any large English railway. It has had little or no litigation with other companies. While complaints have been heard from Lancashire and Yorkshire, where there are so-called competing lines, no witness has appeared to complain of the North-Eastern; and the general feeling in the district it serves appears favorable to its management.

The Great Central Railway, which was opened for all classes of traffic in April 1899, has a total mileage of 665 miles. Of this mileage 465 belongs to it and 200 are jointly owned with other companies. In addition, the company owns 111 miles of canals and tramways. It is, therefore, a system essentially made up of joint lines and canals. It is also the newest line in England, and may stand for the most recent type of development in that country.

It now seems certain that in no very long time all intramural transit in London which is wholly or partly underground, aggregating nearly 225 miles in length, will be consolidated into no more than two great substantially non-competing enterprises, dividing the territory in a way between them, upon a line (roughly speaking) which runs northwest and southeast through Piccadilly Circus, or dividing, along non-competitive lines as much as possible, about Piccadilly Circus and converging severally therein. The Joint Parliamentary Committee of 1901 reported that it was desirable that the working of underground railways in and around London should be put under the control of some one consolidated interest; and if we read into the future of these underground lines the railway experience of the past in England above ground, that is sure to be the ultimate solution.

The English courts commenced, about the

middle of the last century, to break down the old common law doctrines theretofore in vogue against monopolies, which were invoked in opposition to railway consolidation. Gradually the whole legal theory upon which those doctrines were attempted to be sustained has been overthrown, until now there is in England no legal objection possible to be urged, and very little popular prejudice to the amalgamation of railway lines whenever and wherever it seems to be economically desirable. The legal arguments against these consolidations were always drawn from the old decisions against monopolies and restraint of trade, which more than 50 years ago began to be repudiated *in toto* by the English judges. Thus in a leading case often referred to, which was decided in the House of Lords about 1850, Lord St. Leonards used the following notable language:

My Lords, there are just a few remarks that I wish to make upon public policy. I will not add a word to what has been already said by my noble and learned friends, but I will call your attention to what fell from one of the learned judges (Mr. Justice Cresswell) as regards the restraint of trade. That learned judge says that with regard to the restraint of trade, there is a maxim in common law, and he refers to a case in Year Books (2 Hen. V., pl. 26), to prove it; but the learned judge did not tell your lordships upon what that maxim was founded. Nobody supposes that there was any statute upon the subject in those times. Upon what, then, was that maxim founded? Why, upon public policy for the good of the realm. It was not good for the realm that men should be prevented from exercising their trades. Now, let us see what this particular case is; it lies in few words and remarkable consequences have resulted from it. It was an obligation with a condition that if a man did not exercise his craft of a dyer, within a certain town, that is, where he carried on his business, for six months, then the obligation was to be void, and it was averred that he had used his art there within the time limited, upon which Mr. Justice Hull, being uncommonly angry at such a violation of all law, said, according to the book, "Per Dieu, if he were here, to prison he should go until he made fine to the king, because he had dared to restrain the liberty of the subject." I wish to draw your lordships' attention to this case. Angry as the learned judge was at that infraction of the law, what has been the result of that very rule without any statute intervening? That the common law, as it is called, has adapted itself, upon grounds of public policy, to a totally different and limited rule that would guide us at this day, and the condition which was then so strongly denounced is just as good a condition now as any that was ever inserted in a contract, because a partial restraint, created in that way, with a particular object, is now perfectly legal. Without any exclamation of the judge, and without any danger of prison, any subject of this realm may sue upon such a condition as Mr. Justice Hull was so very indignant at in that particular case. That shows, therefore, that the rule which the learned judge, whose opinion is now before the House, thought depended upon some rule of common law, regardless of policy, was founded upon public policy, and has been restrained and limited and qualified up to this very hour, and beneficially so, by that very policy which it is supposed had no bearing at all upon the foundation of the rule. (*Egerton v. Earl Brownlow*, 4 H. L. Cas., 1, 237, 238.)

Within the last five years the notable consolidation of the London, Chatham & Dover and the London & South-Eastern lines has been effected, which operates to merge two theretofore independent parallel and competing lines and to allot the whole southeastern section of England to the amalgamated company. This, as is usual in that country, was accomplished through special Parliamentary powers, which in this case were sought and obtained without arousing any great opposition, engendering any considerable heat, or provoking any declamation about a sacrifice of the rights of the public.

RAILWAY CONSOLIDATION

In point of fact, nothing but good seems to have flowed from it.

Previous to 1899 both these railways had achieved an unenviable notoriety for the inadequacy, slowness, and unpunctuality of their services, for the dilapidated condition of their stations and rolling stock, and generally for the backward state of their accommodation. In the case of the Chatham Company the financial position was also precarious, and though the South-Eastern at one time was nominally much stronger in this respect, it too had lost much ground in the preceding five years, and for 1901 its ordinary dividend at the rate of only 2 per cent was the worst in its history. Competition of the worst kind between the South-Eastern and Chatham companies was a normal state of affairs, and as the result both railways spent vast sums of capital and revenue for which there is at the present time little to show except duplicate lines and stations, and inadequate provision for traffic where extended accommodation was most required. Many times a fusion of interests had been urged upon the two companies, but without result. Negotiations for amalgamation were entered upon several times, but they always broke down at the crucial moment.

At last, in 1898, an agreement between the two companies was come to, not for a complete amalgamation, but for the pooling of gross revenue and working expenses and the division of net profits on a fixed percentage basis, with additional arrangements for the joint contribution of capital required. It was not the intention of the two companies to seek Parliamentary authority for this arrangement, as they were not bound to secure the sanction of any other body than their shareholders. But the government virtually intimated that the new arrangement was so important and far-reaching in its bearing on the interests of the public, that the terms of agreement ought to be embodied in a bill. This bill received the royal assent on 1 Aug. 1899, and seven months thereafter the new arrangement came into operation.

The preamble of the bill recites that

With a view to avoiding undue competition and unnecessary expense and delays and other inconveniences arising from diversity of interests and to turning to the best account the respective powers and resources of the two companies . . . it is expedient and will be for the public advantage that, subject to the provisions and enactments in this Act contained, the undertakings of the two companies should be used, worked, managed, maintained, and improved from and after the passing of this Act, as one undertaking . . .

The Act constituted a Managing Committee to administer the two railways as one company, that new body being made up of the directors of the two companies.

The committee of 1872 sum up their view upon the effect of hostile or prohibitory legislation on this subject as follows: "A long and varied experience has fully demonstrated the fact that, while Parliament may hinder and thwart it, it cannot prevent it." The theory of the British Constitution is that Parliament is omnipotent, and here there is formal admission that there are things that omnipotence cannot do.

France.—The French railway system was developed a little later than the English, but we must look as far back as the reign of Louis XI.,

in the latter part of the 15th century, if we are fully to understand and appreciate that development. That sagacious and masterful prince, who reigned from 1461 to 1483, broke effectually the power of the great feudatories, and by a consolidation of authority in the crown laid the foundation of the absolute monarchy. His taking the postal service out of the hands of the feudal authorities and away from the cities and making it a matter of national administration, these 400 years ago and more, was one of the most notable acts of his reign, and was in a way the first step toward the modern railway system of France. "Modern history," says President Hadley, in speaking of the nationalization of the French post-office, "—the history of nations as such—may almost be said to have begun at this point." What Louis XI. did for the power of the crown and for the postal service of the country, Louis XIV. and Colbert did in laying the foundation of the national system of highroads and canals. The *Ecole des Ponts et Chaussées* was founded, and trained engineers graduated therefrom laid out, constructed and perfected that splendid system of canals and highways, radiating from Paris and reaching every corner of the kingdom, which long ago made France the first country in the world in its roads and waterways. There was from the beginning complete organization, intelligent survey and construction and strict supervision; so that an almost perfect system of lines of communication existed in France before railways were known. In no other country had such results been accomplished in road-making, and nowhere else was such completeness of organization and development possible. The genius of highways had in some sort come down to France as an inheritance from Rome, whose military roads were one of her most characteristic monuments. In this state of case, with a perfect system of roads and canals already built and in operation—which made railways seem less necessary in France than in other countries—it is not strange that the French built railways slowly and cautiously. So it was not merely accidental that France moved tardily in this matter. It is not in the French character to make radical changes, or to do things piecemeal; and it was easy for her highway engineers to see that other nations were blundering in their first railway construction. The racial qualities that distinguish the French, their spirit of order and economy, their notion of proportion, and their conservative good sense in business, all had something to do with their making haste slowly in railway building. It is very much the French way to let other people make the initial experiments in new things, and only to take a thing up when it is demonstrably sound and feasible. It is almost a racial instinct, and this is what happened in the development of French railways. The result is that they now possess the only railway system in the world which was intelligently conceived from the outset as a unit, which was scientifically planned and laid down by competent engineers working together to a common end, and which was built as a whole. The conditions in France that made this possible had their genesis in the dominating sagacity and spirit of order of Louis XI. The highways and canals

RAILWAY CONSOLIDATION

led up to the railway lines, and the governmental regulation and control of the old land and waterways grew naturally into the present system of railway supervision. The system of roads and waterways existing in 1830 suited the French nation exactly. They were so arranged and classified that each bore its exact proportion of importance, whether national, departmental or local. They were regulated from Paris with ease and with military precision. Never was there so efficient a corps of engineers for carrying out such a scheme as that which is trained at the *Ecole des Ponts et Chaussées*. The first step taken by the government looking to a general railway system was the appropriation of a sum of money to pay the government engineers for laying out a general system of railway lines covering the whole of France. When this survey was completed, and while the lines existed only on the maps and blue-prints of the engineers, the government next took up the question of ownership and management. While other countries had been acting and experimenting and making costly mistakes, France had been reasoning and thinking the matter out. There was a long series of debates in Parliament between 1837 and 1840. The plan finally adopted was the conception of Thiers, and was settled upon in 1842. The plans then and thus deliberately conceived and matured—both of engineering and of legislation—have since been carried out consistently. They were sufficiently elastic to be practicable. It was at the outset a policy of support and control without actual ownership, or, in other words, a policy of subsidies to encourage private companies, and in return for these subsidies a reservation of more or less important rights of state control. As the work proceeded and as new conditions arose, amendments and modifications were incorporated into the plan as originally conceived. In 1842 it was strictly a plan for subsidies; in 1852, extensions of chartered privileges were granted to the companies; in 1859, a scheme for the guarantee of interest on the bonds was inaugurated, and, in 1883, the government guarantee was extended to dividends.

Under the plan adopted 33 different companies were chartered, contemplating about 2,500 miles of line. Building went on rapidly until the revolution of 1848, and then again after the accession of Napoleon III. in 1851. The lines have from the beginning been laid down with the idea of avoiding all duplication and all waste of capital; they were surveyed and traced by government engineers, and each part stood in its proper and intelligent relation to the whole. Parallel lines were forbidden as a matter of course, and competition was not conceived of as among the possibilities of the situation. By 1852 the number of independent systems had been reduced from 33 to 11, and in 1859 the 11 were reduced to 6, of which 5 radiated from Paris. Each had a monopoly in its own territory. Competition running riot, the construction of needless lines as a mere speculation in the securities, rate wars, with their attendant iniquities, and the consequent wanton waste of money and effort in construction and operation are essentially unthinkable to a French railway engineer or official. New construction is undertaken only as required, and to meet the necessities for more lines growing out of the development of any particular territory. About 1859

it became obvious that a considerable amount of new construction was necessary in order to bring the railway system up to a proper standard of utility and efficiency, and in order to secure this construction, each of the six companies, and each in its own district, undertook to construct a large number of branch lines. The government took the initiative, and in order to facilitate this new work and to secure it promptly recourse was had to a system of state guarantees of interest on the bonds upon which the money for the new construction was to be raised. This was the plan devised by De Franqueville. Money was, of course, easily raised by issues of bonds upon which the government guaranteed 4 per cent, this guarantee making the securities instantly marketable and extremely valuable. There was, accordingly, no wasteful financiering, no iniquitous jobs, no lack of funds, no foreclosures, no reorganizations, receiverships or squeezing of investors. In 1865 a further plan was proposed in the Chamber for the construction of a network of local roads not to belong to the six companies, and the municipal authorities were given the right to subsidize such lines. Pursuant to this plan, several thousand miles of these local lines were built throughout the country within the next five years. It was not, however, contemplated that they should be combined into systems which might interfere in any way with the monopoly of the six companies. They were designed to be feeders. However, after the war of 1871, the prohibition to combine was successfully evaded, and these local lines by a series of combinations began to be serious competitors in many places to the main systems. This made it necessary for the government to take the matter again in hand, and the problem was ultimately solved by having the great companies take over the local lines within their territories severally, upon terms. In 1879, by a decree of July of that year in the Chamber of Deputies, De Freycinet undertook to raise a loan of 3,000,000,000 francs for the construction of about 10,000 miles of additional line. This plan has been slowly carried out since that time. There was at first some delay, but by the beginning of 1884 this last comprehensive scheme of railway development was settled upon, the leading points of which were these: first, that the state hereafter should confine its own railway operations to the small district in the southwest occupied by what is known as the state line; that isolated lines which the state owned in various parts of the country should be taken over by that one of the six great companies in whose territory it lay; second, that additional lines as needed should in future be constructed only by the companies in whose district they belong; third, that the state should guarantee each company a minimum dividend, and that when the amount available for dividends exceeded a certain percentage—the rate differing for each line—two thirds of the excess should go to the state. The limit, however, was placed so high that this provision has been practically inoperative. Thus, for example, on the Northern line, the guarantee minimum dividend is 13.5 per cent, while the point beyond which the state shares the excess is 22.1 per cent. In the case of the Paris, Lyons & Mediterranean, the guarantee minimum is 11 per cent, the state sharing in anything beyond

RAILWAY CONSOLIDATION

15 per cent, and so on, with slightly lower percentages for the other companies.

All of the lines in France with one exception are owned and operated by private companies. They are *concedés* and become state property upon the expiration of the concessions. Meantime they are subject to a strict governmental supervision and control. The length open for traffic on 31 Dec. 1901, was 23,880 miles, which fully meets all the requirements of the country. The original scheme was for the government to contribute about 250,000 francs per mile; and private enterprise to find about 200,000 francs per mile, thus dividing the expense and the ownership. The concessions generally were to fall in, first in about 40 and later on in 99 years. When this occurs—about the middle of the present century—the government will, it is claimed, become possessed of an asset in the shape of railway property sufficient in realizable value to pay off in full the national debt. In 1892 the French railways were conservatively valued at 16,000,000,000 francs. The original plans of construction and joint ownership were somewhat modified as time ran on. In the construction of the French lines there has been less waste of capital and better results for capital than elsewhere in the world. French railways have cost less and come to more than any others on earth. It need not be argued that the French scheme put in practice would inevitably reduce the cost of construction to a minimum and would secure the best results for the least money. Passing by the matter of the state guarantee of interest and dividends, it may be said that the net earnings of the six private companies have been upon an average far beyond anything accomplished elsewhere in the world in that respect from railway operation. Furthermore, in face of the strong position of the French railways as monopolies, the government notwithstanding exercises a sufficient control—one which is in many respects admirable. No other country has in its civil service such a body of trained engineers and inspectors, and nowhere else are things done so well along these lines as in France. The French plan, as is seen, forces the numerous independent companies to work in harmony with one another, while giving each of them an absolute monopoly in their own territory. It renders, therefore, the process of consolidation within that territory easy and inevitable. Whatever slight attempts have been made in the Chamber to check or prevent combination or monopoly have been promptly overruled as contrary to the general scheme. This was particularly the case in 1875, when Phillipart, a Belgian capitalist, undertook to consolidate the local lines as against the six companies; and even the state itself in the operation of its own lines in the southwest has never succeeded in breaking into the monopoly of the Orleans Company in that territory. While France prohibits effectively competition between her railway lines, she is constantly spending large sums in improving internal water communication; and private carriers using these waterways without paying any toll carry off more or less traffic from the railways, and are allowed to do so. To make a summary statement, we find the facts to be that in France the railway system was intelligently planned as a unit from the outset; that the lines were laid down by competent gov-

ernment engineers and constructed without paralleling; that in consequence very little money was wasted in construction; that competition did not enter into the scheme as originally devised, and that when it arose—notably through the consolidations of the network of local lines built between 1865 and 1870—it was suppressed by the government; that railway investments have been almost uniformly profitable, and upon the whole much more profitable than in other countries; that freight rates are not excessive and that passenger rates are very low; that the public is well served, the passenger service especially being of the very best; that governmental regulation is not hampered or thwarted by the strength of the railways as monopolies; that no mischief and much good seems to have come from the elimination of competition between lines, and that upon the whole the French scheme secures a maximum of adequate, efficient and satisfactory service at a minimum of cost and friction.

Belgium.—The policy of government ownership is perhaps best typified by the Belgian system. Of all countries in the world Belgium probably offered the best field for a state railroad. The country is small, compact and rich, the population crowded, active and intelligent, and the industries varied, all which insured a large volume of local traffic. Moreover, Belgium is on the highway between England and Germany, so that, in addition to a dense local traffic, the Belgian lines were certain to secure considerable through traffic on commodities moving between England and Germany. There was in consequence of all this little room for mistake in locating the main lines, and they were, as in France, for the most part laid down intelligently and built economically. Railway construction began as early as 1833. Private companies were allowed to build lines wherever the state did not choose to build, but competition between the lines owned by private companies and the state lines was not at any time part of the original scheme. Like the French, the Belgians saw from the start that competition would be uneconomic and wasteful. The private railways increased rapidly from 200 miles in 1850 to 700 miles in 1860, and 1,400 miles in 1870. This rapid growth of the private lines was accompanied by their inevitable consolidation into systems, and in spite of the fact that competition had not been contemplated, there began in Belgium about 1856 a period of railway war between the state and the private lines and among the private lines themselves. Theoretically, the state had and exercised the power to forbid the private companies from entering into any competition with the state lines, but, in spite of that, competition in Belgium after about 1856-7 was keen. The state had the better routes and in some sort the inside track, but some other advantages possessed by the private companies practically offset this advantage. This competition working the usual mischief finally drove the government to the expedient of buying out the private companies. This began about 1870. By 1874, the government owned more than half the mileage of the country. By 1880, it owned two thirds, and in 1902, there were 2,516 miles of railway in the country, all or practically all, of which is controlled by the state, either through ownership or lease, and

RAILWAY CONSOLIDATION

competition is in consequence wholly eliminated. The state now owns more than 70 per cent of the total mileage, and operates almost all of the remaining 30 per cent by lease. This is in brief the history of the development of railways in Belgium. It appears that competition was not part of the original scheme; that it nevertheless arose and ran its course; that when the state realized the disadvantage of it, steps were taken to eliminate it entirely, and that this was done by the purchase of the competitive lines. There was at first the inevitable consolidation of the private lines, eliminating competition between those lines themselves, but intensifying it as between them and the government lines. Then came the consolidation of these lines with the state-owned lines by government purchase, and competition was at an end. It is another case of the universal tendency to combine, and of the powerlessness of government to prevent it.

Italy.—In 1878, a Parliamentary commission in Italy undertook an investigation of the railway situation in that country. Testimony was taken throughout the kingdom, and an enormous mass of material collected. In 1881, this commission made its report to the government, which was subsequently published in seven quarto volumes. It was the most thorough railway investigation ever undertaken in the world, and the report is probably the most valuable in existence. The material parts of it have been translated into French, and are thus available. From the work of this commission it appears that, prior to the wars which resulted in the union of the Italian states in 1870, the principal railway lines of Italy not only were disconnected and independent of each other, but also constituted isolated or strictly local systems for each of the chief independent states. Thus the lines in Tuscany, in Lombardy, and in Piedmont were wholly distinct both from one another, and also from those centring in Venice, Rome and Naples. Some of the early charters had come from the Emperor of Austria and one from the Pope: the lines were inadequate to the demands of the business of the country, the service was very poor and the companies substantially bankrupt and irresponsible, but there was plenty of competition. The problem after 1870 was to unite and consolidate these scattered and local lines into systems fit for united Italy, to construct new lines, to reconstruct old ones, to re-equip and to reconstitute; and then to operate the reconstructed lines as a whole. The range of mountains from north to south which constitutes the back-bone of the Italian peninsula dictated a natural division of territory for the amalgamated lines. There was as of course much local jealousy to overcome. Although Italy was too poor to spend much money in experiments, there was thought to be danger to the autonomy of the new state in permitting foreign capital to come into the railways, and it was prevented by the government, so that, in consequence of all these matters and hindrances, things at first moved slowly. Connecting links were first built, which served to unite the isolated local systems, the plan being to consolidate the local parallel and competing lines rather than the connecting lines. Finally the roads fell into four systems—that of Upper Italy, that of Rome, that of the east coast, and that of Sicily and the south. Here, as elsewhere in Europe,

competition between parallel lines did not enter into the scheme of construction and reconstruction, and consequently consolidation was not only inevitable but easy, and it was facilitated wherever there was duplication. Upon the division of territory between the four systems, and with the consolidation of lines within those four territories respectively and the building of the connecting links, the problem of construction was in a way to be solved; or, in other words, the lines were laid down and ready for operation. Next came the problem of ultimate ownership and present maintenance and operation. Soon after 1870 the state had begun to buy up the lines, especially in the north, where there was danger from Austrian influence, and by about 1875 a considerable part of the mileage of the kingdom was owned and operated by the state. So that by that time Italy seemed committed to what may be called the Belgian system of state ownership and operation. But Belgium was rich and Italy was poor, and it was soon found that the state was neither managing the lines well nor making any money out of it; there was, therefore, general dissatisfaction throughout the country with the railway system; neither the poorly served public nor the depleted treasury of King Victor Emmanuel was satisfied. It was in that state of affairs that the investigation of 1878 was undertaken, the result of which was that the Italian statesmen who had the matter in hand came to the conclusion that it was not the proper function of the Italian state to run its railways; that state management in Italy had proved more costly and less satisfactory than private management, and that the carrying on of so vast an undertaking by the new state involved political risks and dangers of a serious nature. The outcome was the chartering in 1885 of three private companies, one, the Adriatic, for the territory on the east of the Apennines, a second, the Mediterranean, for the territory on the west, and a third, the Sicilian, for Sicily, the two systems in the peninsula being of about equal consequence, while the one in Sicily was, of course, smaller. A fourth company has since been chartered to operate the lines in Sardinia. These companies were to take over the rolling stock of the lines within their respective territories at a valuation, and thus become the owners of it, and to maintain and operate the lines, dividing the gross receipts with the state on an agreed basis. So that the ultimate solution was that the state was to own the lines, while private companies were to operate them. Practically the railway business of Italy proper is in the hands of two companies, one on either side of the Apennines, the lines meeting at Naples, Rome, Florence, Milan, and elsewhere. Between 1881 and 1897 the length of the Italian railway system almost doubled itself, and in 1898, there were 9,813 miles of line open for traffic. The service is satisfactory and the railway system is making rapid progress throughout the kingdom. Thus we see that in Italy, competition preceded combination: that it was found to work mischief and that attempts at combination were the inevitable result; that when the matter was taken seriously and intelligently in hand by the state, competition was eliminated by law, and the territory divided; and that then, and then only, were satisfactory results secured in railway operation. It appears, therefore, that

whether we choose state operation as in Belgium or reject it as in Italy, it is the same as far as competition and combination are concerned; that the same economic laws govern in each case, and that in the long run competition is eliminated.

Germany.—Railways in Germany grew up very much as they did in England, at first without any general plan, and without any real comprehension or appreciation of the problems involved. The Germans, however, like the English, seem to have started right on the question of competition. Their earliest statutes explicitly recognized the right to a monopoly in their first lines. The country then consisted, aside from the central kingdom of Prussia, in large part of a number of semi-feudal principalities, and local railway systems sprang up in each of the states, which now constitute the present German Empire, so-called. Prussia followed Belgium in a general way in her early legislation and initial construction. The first state railway in Germany was built in Prussia about 1848–50, from Berlin toward the Russian frontier. Other state lines followed, but, *pari passu*, many private lines were laid down, some of them securing some state aid, by way of guarantees or subsidies or stock subscriptions from the principal states. Some, however, even of the smallest principalities, at first owned their lines outright and operated them too. So there was at the start every sort of a railway in Germany. This haphazard and piecemeal work begot the inevitable result—fierce competition everywhere among the private companies and between them and the state roads. The results were extremely dissatisfactory; the service was poor and the rates high. About 1861, Bismarck came into power, and from that time dates the influence of militarism upon the railway system of Germany. It has since shaped and colored the whole development and operation of the German lines. He saw clearly enough that the mixed and competitive system was a bad one, not only from a military point of view, but also from the point of view of the country at large. Steps were, therefore, gradually taken, in Prussia especially, to acquire the private lines and to consolidate competing and conflicting interests. The matter moved slowly because the country was poor, but the mileage nearly doubled between 1865 and 1875. After the war with France in 1871, more rapid progress was made in unifying the railway system of the country. By 1878, there were about 3,000 miles of state-owned and operated lines, 2,000 miles of privately-owned and state-operated lines, and about 6,000 miles of privately-owned and privately-operated lines. In 1881, the government owned more than 7,000 miles of line, only about 3,000 miles remaining in the hands of private companies. In 1885, the government owned 13,000 miles of line in Prussia alone, while only 1,000 miles remained in private hands. In 1900, there were 30,597 miles of railway in the German Empire, more than 93 per cent of which were owned and operated by the state. Under the present law the government is required to manage the railways "in the interest of general traffic as a single system," and in 1886 the government issued a Code of Railway Regulation, applicable to the whole railway system of the country. Competition practically ceased in Germany by about 1875,

and for the past quarter of a century the railways of the country have been operated on non-competitive lines. Pooling arrangements with the canals and other competing waterways are sanctioned, in order fully to eliminate wasteful competition and unjust discrimination.

Austria.—In 1901, Austria-Hungary had 39,014 kilometres of line open for traffic. The first Austrian charter was granted in 1836, and construction went on actively thereafter until the revolution of 1848. The original idea was to follow the French system, and have the lines built and operated by private companies. Their statute of 1838, it may be noted, was the first general railway law enacted in any country in the world. It provided for undertakings by private companies, and for guarantees by the state of interest upon the cost of construction; it limited dividends on shares to 15 per cent, and absolutely prohibited the construction of parallel lines. It was discovered, however, as time ran on, that the French system was not well suited to the condition of things in Austria; and in spite of statutory prohibition, as the lines were constructed and put into operation, competition ran riot. There was also the usual iniquity growing out of constructing lines for a chance to speculate in the securities; and the competition of the waterways—of the Danube and the canals—although pooling between them and the railways was allowed and encouraged, added to the confusion and disorder of private management. So in 1873, Austria fell into line with the other countries of Europe, and started off in the direction of state ownership and control. In 1885, about three quarters of the mileage in Austria was, however, still in the hands of private companies, but all the lines in Hungary were at that time owned and operated by the state. By 1898, more than half of the Austrian lines were under state management, and the tendency sets more and more in that direction.

Russia.—In May 1900, Russia (including Russia-in-Asia) had 41,400 miles of completed railway, and 8,000 miles under construction, including the great Trans-Siberian line, which is the greatest railway enterprise yet undertaken anywhere. Work began on this line in March 1891, and it is now open for traffic. The estimated cost is about \$500,000,000. The distance all rail from Paris to Port Arthur or Vladivostok is about 7,000 miles, with a through-car service from *la Gare de l'Est* to Port Arthur and Peking. The government furnished a large part of the capital required for construction, and owns and operates about two thirds of the total mileage in European Russia; it has in addition subsidized and thus controls and dominates the policy of the lines owned and operated by private companies. The tendency, as elsewhere in Europe, is toward complete government ownership and operation. There is, therefore, in Russia, it will probably go without saying, no such thing as hurtful competition, and, consequently, none of the evils incident thereto.

The Minor Countries of Europe.—Elsewhere in Europe we find the same variety in railway operation and control as in other things; but the tendency everywhere is to government ownership or to such a strict government regulation as effectually eliminates anything like competition between the lines. Thus in Norway, in 1902, there were reported 1,203 miles of line,

RAILWAY CONSOLIDATION

all now owned and operated by the government; whereas in Sweden, at the end of 1901, there were 7,217 miles of line in operation, of which only 2,392 were government lines. But although in 1893 there were reported to be not less than 108 different owners of private lines in Sweden, the law strictly and successfully prohibits competition between them, or between them and the state lines. The last available figures for the Spanish lines show 8,607 miles open for traffic in that country, all, as in Portugal, owned by private companies, but supported and controlled by the state. In Switzerland, where in 1899 there were 2,396 miles of line in working order, the governmental supervision has until recently been much the same as in Spain. In 1898, by popular vote, it was determined (in view of the evils of over-construction and some hurtful competition in spite of legislative prohibition) to purchase for the government the five chief lines, thus putting Switzerland in the Belgium class of countries owning and operating their railway lines. This scheme is now being financed and carried out by the Swiss government. The railway history of these relatively unimportant European countries is of much less interest and value to us than that of the greater states. The Italian system has been followed substantially in Holland, and in Denmark, and by some of the other minor Scandinavian countries.

India.—The construction of railways in India, which commenced in 1853, has been conducted on three different systems: first, the employment of companies under a system of guarantee; secondly, by the state through its own officials; and thirdly, by assisted companies either with or without guarantee or subsidy from the state, and working with capital wholly raised by themselves or partly with capital provided by the state. Out of eight lines constructed on the first system, five have been purchased by the state. Two of these are worked by companies. The more important, the East Indian line, is carried on by the same company that constructed it in the first instance, on special terms as to the sharing of profits. The second, the South India line, is in the hands of a new company, whose capital was subscribed by the shareholders of the old one. The three remaining lines are worked by the state, and all five come into the category of state lines in the accounts of the government of India. The total number of miles of Indian railway open for traffic on 31 March 1902, was 25,529. Although construction began about the middle of the last century, the system has been developed almost entirely since what English writers on railway problems speak of as "the rise and fall in England of the great fever known as the railway mania," to which detailed reference has hereinbefore been made. The Indian railways were, therefore, planned and constructed in the light of the experience afforded by the home construction and development, and many of the cruder home blunders were thus avoided. They now fall into one or other of four classes: (a) State-owned lines, worked by companies; (b) state-owned and state-operated lines; (c) lines constructed by guaranteed companies, and (d) lines constructed by assisted companies. The English government, following the French led in that respect, provided for a system of guarantees,

by which the necessary funds were cheaply found; in laying down the lines paralleling was avoided, and competition effectively prevented. Where there is no competition there is the less incentive for combination, and there seems not to have been any great tendency in the Indian lines to combine. India, therefore, stands negatively for the soundness of my position. These railways seem to be rather poor affairs; there is much complaint of indifferent service and high rates. How far these things may be chargeable to the inefficiency of the government or may be due to the system itself does not appear. They have up to the end of 1899 involved a yearly loss to the Indian revenues, but the working of the year 1900 resulted for the first time in the history of the Indian Railway system in a net gain to the state of Rs. 87,239, and in 1901 Rs. 1,154,119. From the commencement of railways in India, about half a century ago, to the end of the year 1899, the loss to the Indian revenues amounted to Rs. 57,811,487. Whatever else may be true of the Indian lines, they have been constructed and are operated entirely on the principle of non-competition and division of territory, and there being no competition there has been little tendency to combine; in other words, the evil of competition not existing or not being allowed to exist, there is no call for combination. This is, as I have said, negative evidence in support of the contention that wherever competition is possible combination is inevitable.

Mexico.—The present railway situation in Mexico is fully disclosed in an exceedingly valuable report recently made to the government by Senor Limantour, Secretary of Finance. It purports to have been based upon a careful investigation of the facts, and is on the face of it as intelligent and comprehensive a state paper as any that has emanated in recent years from any government office anywhere in the world upon the subject. The fact that Senor Limantour, who is now virtually prime minister of Mexico, has been nominated by President Diaz as his successor in the presidential office suggests his high standing at home and gives weight abroad to his views on these questions. This report, which seems largely to speak the voice of the secretary himself, deals at length with the problems of competition and combination, and discloses the fact that the policy of the Diaz administration, as now settled and determined, is to meet and solve these problems by absolute government ownership, rather than by any further futile attempts at legislative control. The government, finding that the general railway law of 1898 (from which, when it was passed—as in the case of our original interstate commerce law—great things seem to have been expected) was proving inadequate to the due regulation and administration of the lines, and realizing the necessity of stronger and surer governmental control, has lately come to the policy of going into the open market and of adopting the same tactics as private individuals or companies in purchasing the shares of such lines as it desires to control. Mexico is, therefore, now fully committed to the theory of governmental ownership, if not to that of governmental operation. The government is just now offering to purchase the Vera Cruz & Pacific line, which has just been completed by American capital and lost to its

RAILWAY CONSOLIDATION

original owners by the recent suspension of the Maryland Trust Company of Baltimore. Those portions of Senor Limantour's report which disclose the processes by which the government has acquired and is acquiring such a proportion of the shares of the leading lines as will give it due preponderance in their control are very interesting. The explanations of the causes which have moved the government to this step, as contained in the report, are of an even wider interest and significance to students of the railway problem. In brief, Senor Limantour's explanation is this: The government has until recently been in the usual elementary attitude of encouraging by concessions, subsidies and otherwise all the railways which either citizens or foreigners would undertake to build and operate as private enterprises, in the supposed interest of the most rapid possible development of the country. It was only in 1898 that a general railway law was passed, which, however, soon proved entirely inadequate. It was, therefore, in addition found necessary to prescribe new rules relative to granting concessions for competing lines between points already connected, and to establish a tariff commission—something like our Interstate Commerce Commission—which was an attempt, through the agency of a governmental bureau, to prevent combinations in freight rates, and to regulate them in the public interest. In the light of the experience of other countries—and, as it appears, especially in the light of the experience in the United States—competition between the lines is by this report pronounced harmful, "except where traffic is large enough to support it"—whatever that means. Government ownership and regulation is declared to be the only real preventive or remedy against such disastrous competition—with its inevitable result of the consolidation of competing interests. It is further suggested that the fact that groups of foreign capitalists had undertaken to consolidate several of the principal lines, obliged the government to take a definite attitude lest their great railway properties should thus be taken over and controlled by alien capital. It was clearly seen that these contests for territory between the hitherto conflicting interests would eventually and inevitably result in either the forced or the voluntary consolidation of the competing systems. The law as it stood was inadequate to prevent the acquisition in the open market by any private interest of a control of the shares of any company sought to be acquired, and there was no way to prevent the consolidation of interests through voting trusts or otherwise. Specifically, the situation in the early part of 1902, which seemed to drive the government strongly in the direction of state ownership and control, was this: The railways of the country were found already to be in the hands of no more than four groups of capitalists, namely, the Central, the National (having lately absorbed the International), the Interoceanic and the Mexican—all but the last showing great expansive activity. The Central especially, by the recent purchase of exclusive port concessions and the building of new lines in and out of the City of Mexico, was threatening to cripple the National line. Plainly, therefore, consolidation between it and the Central would inevitably follow in the ordinary course. Meanwhile, through Messrs. Speyer & Co., the National was trying

to acquire the control of the Interoceanic route, but this was frustrated by the government. Various circumstances favored the government as against the foreign bankers in its secret move to secure control of the Interoceanic's debentures. "The ability and high financial standing," says the report, "of the firm representing the interests of the Mexican National constituted a serious obstacle to the attainment of our aims, and it was necessary to act as we did with decision, rapidity and absolute secrecy." A proposition for a common exploitation by the government in association with the National, the International and the Interoceanic companies followed; "but it was soon recognized that such an arrangement could not have the necessary durability nor afford the indispensable conditions whereby the companies might secure themselves definitely against the hostility of other corporations to which they might be exposed in time." The government thereupon, wisely declining to be drawn into any partnership arrangement with the companies, reverted to its original plan, namely, an arrangement such as would give the state primary and absolute control of the three systems, and in such a way as to protect each of them against such future competition as would be sure to arise under the existing state of things. The report declares that the government has now determined to grant no concessions hereafter for competing parallel lines, except in territories where dividends can be earned by each such line. Several voting trusts, in some of which the government has had an interest, have existed in Mexico, but some of these have lately been dissolved upon the advice of American counsel.

It was at first proposed that the government should exercise control of the new consolidated system through the voting trust of the National, already in existence. But, "according to the valued opinion of American attorneys, who are specialists in affairs of this nature, it would have been attended with many objections of a legal character, and have proved a fruitful source of litigation." Accordingly, the consent of its three members was obtained, and the voting trust dissolved, an agreement being entered into with Messrs. Speyer & Co. whereby they were to secure for the government 40 per cent or more of the voting shares. The report then enters into a detailed account of the steps by which this was successfully accomplished, 47¼ per cent of the shares being thus secured. It also goes fully into the question of the probable earnings of the consolidated railways and of the issuance of treasury notes for \$12,500,000, American gold, to pay for them. The advantages to the government, growing out of the control of the new consolidated system, is summarized in the report as follows:

1. The having obtained by one stroke the control of the lines belonging to the National and International without losing control of the Interoceanic.
2. Having secured a considerable reduction in the total cost of the operation; and
3. The ability to effect payments in such manner as in no wise to disturb the equilibrium of the budget, and out of funds which in the long run will be recovered by the state.

Repeated reference is made throughout the report to the railway situation in the United States, and it is obvious that our experience has strongly influenced the Mexican government in

RAILWAY CONSOLIDATION

its new departure in the direction of state ownership. They have learned our lesson before we have learned it ourselves; and now that Mexico has come into line with the rest of the world in its attitude upon the question of railway competition and combination, the United States stands alone among the greater commercial countries of the earth in continued persistence in the futile attempt to secure competition between railway lines and to prevent combination and the consequent division of territory; and it leaves us upon the general questions involved and upon the larger issues of the railway problem, quite alone. From a return prepared by the French Ministry of Public Works, it appears that there were in Mexico in 1870 no more than 349 kilometres of line; that in 1880 there were only 1,120 kilometres, while in 1890 there were 9,713 kilometres, and in 1900 a total of 15,454 kilometres of railway in operation—now, as we have seen, all substantially under government control or presently to pass thereunder, as the result of the investigation and comparison of the advantages of private versus government ownership and operation set forth in Senor Limantour's report.

Australia, etc.—In Australia, state ownership and control has since about 1860 been absolute and universal. The latest available statistics show 12,926.75 miles of line open, namely: In New South Wales (30 June 1902), 3,025.75 miles; in Victoria (30 June 1901), 3,221 miles; in South Australia (30 June 1901), 1,736 miles; in Queensland (30 June 1900), 2,801 miles; and in West Australia, 2,143 miles, by the last report. While there was at first some construction by private companies, every mile is now state railway. In New Zealand, in March 1902 there were reported 2,235 miles of state railway, and 88 miles of private lines. The figures intimate that there is no serious competition there.

South America and Africa.—In South America the governments generally own the lines. In Brazil, in 1897, there were 9,072 miles of line open and 3,500 miles in course of construction. Of this mileage the state actually owns but a small part, but it subsidizes the rest, and thus exercises an efficient control over all, which effectually prevents duplication and competition. In the Argentine there were reported in 1901 about 10,250 miles of road, mostly government lines. Chile in 1902 reported about 3,000 miles open, of which 1,438 belong to the state. The French possessions and dependencies in North Africa reported, in 1900, a railway system amounting to 4,628 kilometres in length, as against 3,595 in 1890, and 517 in 1870; British South Africa seems to have had, in 1900, nearly 6,000 kilometres of lines in operation. There were about 2,000 kilometres of line open in the Transvaal at the commencement of the Boer war, and about 400 kilometres in the Kongo in 1900. The total length of all operated lines in Africa, including the foregoing, the Egyptian lines (2,063 miles), and some little development in Portuguese East Africa, amounted in 1900 to 18,467 kilos, substantially all of which is government line. Competition and combination are, therefore, not open questions in Africa. The several European countries that have built the lines there either operate them directly or see to their operation on a strictly non-competitive basis.

Conclusion.—From the foregoing general

view of railway history and development throughout the world, it appears that there is a universal and irresistible tendency in competitive railways in the same territory to combine and to divide the territory between them; that attempts by legislation or litigation to prevent it have uniformly failed; that states which at first recognized and sought to enforce the principle of competition between railways have one after another ultimately abandoned the attempt; that nowhere, except in the United States, is the principle of competition now recognized or still sought to be enforced; that railways in new countries or colonies of old countries, constructed during the last quarter of a century in the light of the experience of the older countries as to competition, have been constructed and operated from the start on non-competitive lines; that the amalgamation of parallel and competing lines is entirely consistent with good service, reasonable rates, and adequate governmental supervision and control; that where railways compete there is always an enormous waste of capital and effort and frequently poor service and high rates; that the tendency everywhere is to eliminate competition where any measure of it still exists; that government ownership is good or bad according to the point of view; that there is a strong tendency in Europe, and elsewhere except here and in England, toward government ownership and operation; that the governments of Europe, with 10 times the police power of our own, have long since abandoned all attempts to hinder and thwart the laws of trade and commerce by restrictive legislation, or to prevent the inevitable in railway development; that, instead of opposing this economic evolution, the most enlightened European governments have on the contrary legalized it, and seek to enforce and regulate it in the public interest; that the best and cheapest service is secured where competition is impossible, and where the state puts the emphasis of its effort, not on interference with railway finance, but on securing good service at fair rates.

Author of 'Law of Railways,' etc.; Professor of American Law in the University of Paris.

Railway Construction. Tracks.—The railway track more than any other part of the railway machine had a crude beginning, and has reached its present condition of excellence by a continuous series of improvements. In the first series of railroad construction, tracks of numerous designs were built, the chief thought of the builders being to secure a solid structure that would not allow the rails to spread. The track was of necessity relatively heavy and expensive in relation to the weight of the rolling-stock and volume of traffic. Three kinds of rails were used, the one most generally employed consisting of strong wooden beams surfaced with strap iron. The iron rails first used were cast and their length did not exceed $3\frac{1}{2}$ feet. Rolled rails were soon substituted for those of cast-iron and the length was increased to 15 feet, with a weight of about 40 pounds to the yard. As late as 1844 all rolled-iron rails used in the United States were imported from England, and were in the shape of an inverted V. The T-rail now universally employed was not much used during the first 20 years of railroad construction. Since 1870 rolled steel has been used instead of iron, and the weight of the rail has been steadily increased to 110 pounds to the yard. One hundred pounds to the yard has become the standard upon tracks where traffic is heaviest. The standard length of rail has been maintained at 30 feet, but at the present time some track is being laid with rails 60 feet in length. Along with the improvements in the track, bridges and other structures have been strengthened to meet the necessities of modern transportation methods.

Construction.—A perfect and safe track should be complete in all respects; full bolted, full spiked, well ballasted, surfaced, lined, and gauged. The best dirt ballasted track is made, when laying it, by bedding the ties to a level surface on top before putting on the rails. If it is intended to ballast track with cinders, gravel, or stone, as fast as it is laid, the tie bedding should be omitted in order to have the full width of the grade upon which to deposit the ballast, but at the same time the ballasting should be kept well finished up to obviate the danger of spoiling the rails. When laying the rails care should be taken to give the proper space at the joints for expansion. Too much space at the joints must be avoided in order to prevent the car wheels from battering the ends of the rails. The coefficient of expansion for steel is .0000065 of the length for each degree. For a rail 30 feet long and a difference of 100 degrees, or from 10 degrees below zero to 90 degrees, the amount to allow would be one-quarter inch. To take up the flow of the rail one-eighth inch must be added, making a total allowance of three-eighths inch. A steel rail expands or contracts $\frac{1}{100,000}$ of a length under a load of one ton (2,240 pounds) per square inch.

This is also its expansion under a rise of 15 degrees of temperature; consequently, if a 30-foot rail is subjected to a rise or fall of 15 degrees, it exerts a force of one ton per square inch if resisted. Where angle bar splices are used on joints, the best method to hold steel and to keep it from creeping down grades or from running ahead enough to throw the track out of line or kink the rails is to use the slot spikes in the splices. Short rails (less than 10 feet in length) should never be used in making connections except in cases where it is absolutely necessary to use short pieces of rail, as at the end of frogs, in the roundhouse tracks, etc.

Spiking and Gauging.—All tracks should always be kept full spiked and in perfect gauge. Bad gauging detracts from the appearance of an otherwise good track, makes track easier to knock out of line and down below the surface, and is the direct cause of wrecks. The spikes should be driven about $2\frac{1}{2}$ inches from the edge of a track tie. Both inside spikes should be driven on one edge of a tie, and both outside spikes on the other edge in order to prevent the tie slewing and also to assist in holding the rail from creeping.

Drainage.—In order to ditch a cut properly, it is necessary to take measurements from the rail to the bottom of the face of the cut, at different points along the cut, and ascertain at what average distance from the track the back of the ditch should be located. The width of a cut and the slope of its face on each side of the track will govern, to a certain extent, how far from the track rails to place the back of the ditch. The ditch should be deep enough to thoroughly drain the track, and the distance from the rail to the back of it should be in proportion to the depth of the ditch, giving the water an easy fall from the track and full passage through the ditch, avoiding all danger of its washing the shoulder of the grade or undermining the track. As a general rule the bottom of the ditch should be 8 or 10 feet from the rails where the grade width will allow it, and about two feet below the bottom of the ties. When the track is ballasted with dirt, the slope should commence in the centre of the track $2\frac{1}{2}$ inches above the ties, falling at the rate of $1\frac{1}{2}$ inches to the foot. From this point, which is three feet outside the ties, and two inches lower, the incline should be greater, about in the proportion of four inches to the horizontal foot. If the track is ballasted with gravel, the slope toward the back of the ditch should commence about two feet outside the track rails, the ballast at this point being level with the base of the rails. To insure a thoroughly good drainage, all the water which falls upon the track or adjacent land, should be conducted through ditches, culverts, bridges, or other channels to the nearest running stream that will take it away beyond all possibility of injuring the track. Where musk rats or minks are plentiful and cause damage to the track by burrowing under it, a heavy coating of cinders and slag along the sides of the embankment is an effectual protection against their depredations. The cinders form an acid in the water and at the same time are too sharp for the animals to burrow through.

Vitrified Pipe Culverts.—The use of vitrified pipe for culverts under railroads has continued in constantly increasing volume since

1878, its advantages are now fully appreciated, and experience has pointed out such treatment as will insure the best results in efficiency and permanency. In northern latitudes especially, where severe cold prevails, the culvert should have a good fall, and be so constructed that no standing water be allowed to remain in the pipes and freeze. When drainage capacity greater than that afforded by one pipe is desired, two or more lines of pipe may be laid side by side. This practice is quite common, and gives an important advantage in that the full capacity of the pipes is utilized at a lower depth of water, but the separate lines for pipe should be laid far enough apart to secure a solid bed for each one. No arbitrary rules can be made for work of this character. Varying physical conditions must be met and each particular work treated separately on its merits. Under especially favorable conditions of good soil, light embankment, and good drainage, there is no doubt that the pipe culvert may be put in without cement and without end abutments, insuring complete construction at a minimum cost, but the durability of vitrified pipe being conceded, the permanency of the work is a prime consideration, and the wisest economy would seem in all cases to suggest the use of concrete as a foundation for the pipe, and that each end of the pipe culvert be protected by parapet walls of substantial stone or brick masonry.

Ballasting.—If stone is difficult to obtain, a good track can be made with gravel and stone combined for ballast. The foundation for the track should be laid with broken stone and above it should be placed a quantity of coarse gravel sufficient to bed the ties, surface the track, and dress it. Cinders are equally effective as a ballast, except in wet cuts, when stone should be used, and are cheaper than either stone or gravel. Six inches of cinders will absorb about one inch of rainfall and will thus keep the foundation beneath the ballast dry. They make a superior ballast on clay fills or gumbo bottoms, and are a positive exterminator of weeds. Where the sub-grade is well drained and solid, an excellent track can be made by ballasting with two cars of gravel in a place, and to accomplish the work in this way, estimates may be taken at the rate of 325 cars of gravel to the mile of track. The embankment should not be less than 14 feet wide on top before putting on the gravel. Although *locomotive cinders, furnace slag, burned clay, and gravel* make excellent ballasts, within the past few years the best results have been obtained from stone ballast where the stones are sufficiently small to pass through a 1½-inch ring. The first cost of stone ballast is large; but, once in place and thoroughly tamped, it is extremely solid, will arrest the springing action of the track, and will insure a nearly perfect drainage.

Laying Rails.—Owing to the difference in quality and in the amount of traffic over the rails, it is quite difficult to form a correct estimate of the average life of the same. Good iron rails have been known to last, in service on the main track of a railroad doing a fair business, 9 or 10 years, and steel rails, 15 to 20 years. There is much discussion on the subject of broken or even joints. The majority of track has heretofore been laid with even joints;

but, at the present time, all rails are being laid with broken joints, which consists in placing the rail joint on one side of the track opposite to the centre of the rail on the other side of the track. Outside of the general line and surface, the principal defects in steel rails are pipes, gag marks, and cinders, which result in flaws. Owing to heavy engines and cars of great weight now employed, heavy rails are demanded to be used and as the height gives vertical strength, in such heavy rails used, height should be the main consideration, and should not be less than six inches. To give good wearing heads, the proportion of metal in the head should be kept down to the minimum, as owing to the present process of rolling steel rails at a great heat from a large ingot, a thick head will not give as good results as a thin head rail. The web should be thicker at the base than under the head, which in the high rail insures greater strength, as the tendency is to break at this point, if too weak.

Wave Motion.—As all the rail movements are on the principle of the lever, there is, of necessity, an undulatory motion on the passage of each train, the amount of which being dependent on the condition of the sub-grade, ballast, ties, rail, and weight of the rolling stock. The less substantial the superstructure, the greater ballast compression there will be, and, of necessity, a rough-riding track. The foundation of all ties being loosely compacted material, any movement or "churning" of the tie necessarily throws unequal loading on the ballast at different times, causes its compression and movement, and destruction of the tie foundation. The wider the ties and the lighter the rail and the heavier the loads, the greater such movement must be. Rails take a permanent set, as regards wave motion, in one of three forms: (a) Joint low and centre high. (b) Joint and centre low, quarter high. (c) Entire rail wavy. As the vibratory motion of the rail takes place, something has to give way. If the fastening to the tie is by push bolt or lag screw, the tie will be raised with the vibration and "pump" the ballast, and in time the fastenings will become loose.

Elevation of Curves.—The elevation of curves has been a subject of much discussion. Twenty years ago, one-half inch elevation per degree of curve was considered proper; but now, with faster and heavier trains, a greater elevation is required. Engineers claim that one inch per degree for a speed of 60 miles per hour is proper for curves of three degrees or less, but for each additional degree the elevation should not exceed ¾ inch. While practice teaches the amount of elevation needed in any given case, it is a safer plan to follow the ensuing formula deduced from mechanics in following the theory of elevation; $E = \frac{v^2}{32.16g}$, in which E represents the elevation in feet, v^2 the square of the velocity in feet per second, g the gauge or the distance between the points supporting the wheel, or from the centre of one rail head to the centre of the other, and R the radius of the curve in feet. This rule, though scientifically correct, cannot always be applied in actual practice, because all trains do not travel at the same rate of speed. Practical provision

RAILWAY CONSTRUCTION

must be made for the average speed of trains and the number in each class of service. For example, if a road have two trains whose speed is 50 miles per hour, four with a speed of 40, and six or eight with a speed of 25 miles per hour, one inch per degree of curve will be found suitable. The pressure by the fast train against the outer rail of a curve will not be sufficient to spread the rail or throw the track out of line. The elevation will be about right for the 40-mile trains, and while it may be excessive for the slow trains, yet they will do no particular damage to the track and will have a tendency to prevent the track being moved permanently outward by the fast trains. The liability of derailment of locomotives or cars is much greater on a curve track than on a straight track, and a large percentage of such accidents is chargeable to the defects in the rolling stock as well as to the defects in the track itself. Heavily loaded cars often leave the track owing to the failure of a truck to adjust itself to the curve of the track, caused, perhaps, by a defective curve roller, and the greater part of the load resting upon one side of the truck.

Frogs and Switches.—The turnout, by which a car may pass from one track to another, consists of a frog, a rail leading to the frog, a corresponding opposite rail, and a device connecting these rails with the main track known as the *Switch*. If the switch is made to serve two turnouts, it is called a *three-throw switch*; a *trailing switch* is one where a train on the main track passes from frog to switch, while a *facing switch* is one that approaches in the opposite direction. The common or *stub switch* consists of a pair of connected rails so arranged that while one end is fixed, the other can be moved so as to be a part of either the main track or turnout. This switch has two serious defects—the want of safety and the necessary space at the end of the moving rail, which jars the rolling stock, batters the switch rails, and causes discomfort to passengers. The first cost of a point switch is more than a stub, but the split which is more economical to maintain, and safer, is cheaper in the end. In laying switches the general rule is to cut the least number of rails. When putting frogs into a track care should be taken to have them in a true line and level with the track rails which are connected to them. The gauge rail, opposite the frog, should be put to a perfect gauge for the full length of the frog.

The *spring rail frog* has been designed with a view to safety. All four ends are spliced solidly together as in a rigid frog. The hinge rail is attached to the main rail by a bolt hinge. This allows the rail to move freely and prevents it from creeping endwise. It is attached to the movable part of the running rail by strong bolts passing through both rails and a wrought iron filling.

Safety Appliances.—The greatest care must be exercised in the instalment of safety devices, as far as practicable automatic, without discouraging watchfulness on the part of engineers and others. The plan of sealing the stopping mechanism and imposing a severe penalty for breaking the seal is an excellent one. The most carefully planned automatic devices should be provided, and no railroad train, traveling at terrific speed, and representing enormous energy,

should be allowed to run without any safeguard between itself and disaster beyond the watchfulness of one man, who may be taken ill, or suffer from a temporary mental aberration, or may even die suddenly and unnoticed.

Transfer and Turntables.—These important adjuncts should be constructed so as to be conveniently driven by motors with an electric motor; no expense is incurred when the table is idle, and the cost per transfer or turn is much lower than when either steam or hand power is used. Many railroads are putting in electric turntables, and careful investigation shows that the cost per turn by electricity is from 30 to 50 mills, while with hand power it is from 10 to 12 cents.

| REQUIREMENTS FOR ONE MILE OF TRACK | | | | | | | | | | | | | |
|------------------------------------|-------------------|-------------------------|-----------------|----------|-----------------|----------|----------------|--------------------|----------------------|--------------------|--------------|-------------|--------------|
| No. ties per 30' rail | No. ties per mile | No. tie plates per mile | 4 spikes to tie | | 6 spikes to tie | | Length of rail | No. rails per mile | No. splices per mile | No. bolts per mile | | Fence posts | |
| | | | No. spikes | No. kgs. | No. spikes | No. kgs. | | | | 4 hole bolts | 6 hole bolts | Ft. apart | No. one side |
| 15 | 2,640 | 5,280 | 10,560 | 28 | 15,840 | 42 | 20' | 528 | 1,056 | 2,112 | 3,168 | 8' | 660 |

Drawbridges and Liftbridges.—Electricity has a specially valuable field in connection with the operation of drawbridges and liftbridges. Speed and control are the requisites of modern methods, and the old plan of operating a drawbridge by a capstan worked by several men is now practically obsolete. A few years ago, the drawbridge at Hamilton avenue over the Gowanus Canal in Brooklyn, N. Y., was operated by from three to five men working on a capstan. Then

RAILWAY CONSTRUCTION—RAILWAY ECONOMICS

it took four or five minutes to complete the operation. The electric motor which has been substituted opens and closes the bridge in 50 seconds, and the services of but one man are needed. When electric current can be obtained, practically all drawbridges now designed are constructed to operate by electric motors.

RAILWAY CONSTRUCTION.

Railway Economics. In one sense railway economy is only a branch of the general subject of political economy (q.v.). The laws which govern railway rates, railway profits, or railway control are fundamentally the same as those which govern the rates, profits, or control of any other kind of industrial enterprise. But among all our important industries the railway is the one which has most quickly and completely felt the effect of modern methods in the handling of capital. For this reason it is useful to make railway economy a subject of special study, because it indicates the possibilities and difficulties which lie before our statesmen in the future, as distinct from those which they have habitually met in the past.

The feature which distinguishes modern industries from those of earlier times is the large investment of fixed capital. Two or three centuries ago we had unimproved farms, small stores and shops, rude boats and wagons. To-day we have highly developed systems of cultivation, large stores and factories, and complex means of carriage by land and water. But nowhere has the change been so marked as in the character of the highways on which commerce is handled. The rough road of ancient days has given place to the turnpike, the turnpike to the canal, the canal to the railway; and with each successive generation the railway itself has become an instrument of increased size and strength.

The effect of all this change has been greatly to reduce the cost of transportation. But this result has not been reached in any simple manner. One set of elements in the cost—the so-called *fixed* charges on capital—has been enormously increased. The country road of our great-grandfathers may have cost from \$300 to \$500 a mile. The turnpike road cost ten times as much—perhaps from \$3,000 to \$5,000. The old-fashioned railway, conforming itself closely to the original character of the ground, with steep grades and sharp curves, could be built for \$30,000 a mile. The modern trunk line, where grades are reduced to a minimum and every engineering appliance is most highly developed, costs \$100,000, \$200,000, or in some parts even \$300,000 a mile. And yet it is the expensive appliance which does the work cheaply.

The general explanation of this paradox is simple enough. The higher the fixed charges per mile of road, the lower is the expense of carriage for each ton of traffic. The old-fashioned road cost perhaps \$25 per mile per year for interest and maintenance; but the expense of hauling a ton over a mile of such a road will run at least as high as ten cents. The turnpike costs perhaps \$300 a year for interest and maintenance, but the expense of hauling a ton over a mile of turnpike will be less than

a third of what it was over the old-fashioned road; because horses on a good road can draw three times as heavy loads as they can on a bad one, with less wear and tear to the wagons and to themselves. The interest and maintenance charges for a poorly located railway may be \$2,500 per year, more or less. The direct cost of hauling each ton over a mile of such road will be in the neighborhood of one cent. Increase the excellence of the location and construction of your railway, and the annual interest and maintenance charges will increase to \$5,000, \$10,000, or even \$20,000 a mile; but the possible train loads will increase so rapidly as the grades and appliances become better that the cost of hauling each ton will be reduced to half a cent, a quarter of a cent, or in some instances an eighth of a cent a mile.

The question which of these methods is the most economical depends upon the amount of traffic which you have to handle. If there are only a thousand tons of traffic in a year, it will not pay even to build a turnpike. For the saving of \$70 which results from the ability to haul those 1,000 tons at three cents instead of ten cents will not pay the \$300 a year interest and maintenance on a mile of turnpike. But if we are to carry 10,000 tons instead of 1,000 there is a saving of \$700 instead of \$70, and this makes the better road the more economical. If we can get \$100,000 it becomes profitable to have a railway; and if we can get 1,000,000 it will pay to have that railway constructed with a very high degree of excellence. The more traffic there is, the more does economy in the direct cost of hauling count as a justification for an increase of fixed charges.

In a newly settled or slightly civilized community the possible traffic per mile is small, and the appliances must be correspondingly rude. Economy of fixed charges is of more consequence than economy of operation. But as time goes on these conditions are reversed. Increase of population means increased demand for traveling accommodation. Improvement in the arts means increased production, increased amount of freight to be carried to market and, what is perhaps of still more consequence, increased demand for the hauling of coal and raw materials and of food supplies for the laborers. Under all these circumstances there has been a demand for every invention which would enable a railway by an increase of original cost to do its work more economically. We have substituted steel rails for iron because they enabled us to carry heavier loads. We have for the same reason gradually increased the weight of our cars and our engines. The modern locomotive weighs more than the old-fashioned locomotive and burns a little more coal; but it hauls five and ten times heavier loads of freight.

Occasionally it will happen that railways are built or improvements introduced in advance of the needs of the country, where population is not sufficiently dense or productivity sufficiently high to support them. This was notably the case in the years preceding the crisis of 1857, and again in the years immediately subsequent to the Civil War. In both of these cases the traffic was insufficient to support the lines that had been built in the newer territories, and very serious loss neces-

sarily resulted. But the general effect of railway development has been to create an enormous traffic at low rates, in place of the very much smaller traffic which was possible at the rates that prevailed before the railway was introduced or improved.

To this extent the effect of new methods of railway economy has been thoroughly good. But the good thus done has been accompanied by certain evils, which at times have proved very serious. The direct expense of doing each piece of business—of loading or hauling each ton of freight or carrying each individual passenger, which the railway agent must charge against every such piece of traffic—becomes very small in proportion to that contribution to the fixed charges of the road which there is no available rule for apportioning. These enormous fixed charges must be met somehow. But how much of them should be paid by passenger traffic or how much by freight traffic, how much by small quantities of valuable goods carried at high rates and how much by large quantities of cheap goods which will barely pay more than the direct expense, is a matter for the agents and managers to decide in their discretion. A railway rate really consists of two parts. It is a price for the loading or hauling, plus a tax for the general expenses of the road. The price element must be based on the cost of doing the work. The tax is usually based upon the ability of the goods to stand its imposition—or, in the current language of the market, upon what the traffic will bear. Manufactured articles will bear a rate per ton which would be simply prohibitory if applied to coal or ore. Therefore freight is classified; and instead of a uniform rate per ton we have several different sets of rates for goods of different classes. Short distance traffic will bear a rate per mile which would be prohibitory to long distance traffic. Therefore we make reductions in the rate per mile for long distances which would be ruinous if applied to short distances. Of course the element of economy of handling enters into these classifications and distance gradations; the low grade goods are on the whole cheaper to handle than the high grade goods, the long distance traffic is more economical than the short distance traffic; but the element of ability to pay the tax is the one which is of more consequence than all others put together.

But it is obvious that this taxing power is a very dangerous thing to place in the hands of private corporations, and one which is liable to be abused. To meet this danger and these abuses several remedies have been proposed.

1. *Competition between Different Carriers on the Same Line.*—This was the theory upon which the early railway legislation of England was based. It was supposed that a railway corporation would, like a turnpike or canal company, be primarily occupied with furnishing the highway; and that any carrier who should choose to build cars or locomotives could run his trains on the railway, precisely as he might run his wagons on a turnpike or his boats on a canal. It was impossible to apply this principle, partly on account of difficulties of operation—the danger of accident being very great if independent carriers tried to use the same line—but chiefly because a railway could handle

its own cars and trains with advantages so much better than those which could be commanded by the cars and trains of independent carriers that the latter could not afford to pay the tolls fixed by charter.

2. *Competition between Different Lines.*—This was the theory which was at first favored in the United States. It was a little more workable than the English theory; but it can hardly be said to have produced better results. For if you have parallel railways, so that each producer has the choice of two lines, this duplication of plant involves a great waste and loss to the community; moreover, the competition between two such parallel lines often becomes so ruinous that it is followed by their consolidation. If, on the other hand, we have competition at some points and not at others, the places which get the benefit of the competition enjoy very much lower rates than those which prevail elsewhere, and we thus have discrimination, generally in favor of the large cities and often in the form of secret rebates in favor of the more unscrupulous shippers in those cities, which are an evil of very great magnitude. They tend to increase the drift, already too strong, from the country to the city; they also tend to substitute a system of underhanded dealings in business for an open and straightforward competition between producers on equal terms.

3. *State Regulation of Rates and Fares.*—This system takes two forms, according as this special liability to regulation does or does not carry with it the grant of monopoly privileges. In America, during our later period of railway legislation, we have tried to have such regulation without legalized monopoly. In France the two have been combined.

The danger in the American system of rate regulation, without the guarantee of special rights and privileges, is that the rates may be fixed so low that there is no profit in the business of railway carriage. Under such circumstances railway building will be stopped and the community will be deprived of the necessary development of its facilities. This was felt at the time of the Granger legislation in 1874. It was also felt, though to a somewhat less degree, in the years succeeding the passage of the Interstate Commerce Act. The community attempted to secure low rates without giving railway owners any corresponding consideration. The effect was that it got fewer roads than it wanted until the laws were changed or until population had growth to adapt itself to the new conditions.

A second danger in the American system is that a legislature which regards itself as the representative of the shippers' interests as against those of the railways will be always trying to stimulate spasmodic competition, as was done in the anti-pooling clause of the Interstate Commerce Act, and will tend to perpetuate those very discriminations or differences in charge which it is the main object of railway regulation to check. For it has been proved over and over again that if you have really active competition between agents of competing lines you do not secure that openness and equality of rates which is possible when such competition is abolished.

The French system of rate regulation is different from the American. By French law

RAILWAY (ELECTRIC) ECONOMICS

the whole country is divided into districts. Each railway has a monopoly in its own district, in return for which monopoly and for certain substantial subsidies given by the government the company is subject to certain well defined rights of control. The French system seems equitable in theory, but it cannot be said to have worked well in practice. For the agents of a railway company which holds a guaranteed monopoly have such an advantage in bargaining with the government that they find it possible to exact very large compensation for any concessions that they make to public demands. They get a great deal of profit in return for very little control.

4. *Direct Ownership and Operation by the Government.*—This is the system which has prevailed in Germany, especially during the last quarter of a century. Prior to that time Prussia and other continental countries had contented themselves with owning parts of their railway system, leaving other parts to be built and operated by private enterprise. The effect of this mixed system was that the state railways became virtually one private corporation among many. The companies dictated the policy of the government, instead of giving the government any opportunity to control the policy of the companies. To avoid this evil the Prussian government purchased substantially all of the railways of that country, and many other states have tried to follow the example of Prussia to the extent of their financial ability.

The excellence of a government railway system will, roughly speaking, depend upon the excellence of the government itself. If the administration is in financial straits the ownership of a railway system furnishes a temptation to tax the people which is too near at hand to be resisted. If, on the other hand, the government is in a sound position financially, it will adopt a much more liberal policy in the matter of charges. Such a government will probably try to meet popular demands more fully than some of our private corporations. But it is slower in perceiving commercial needs and wants, and hence will not respond as promptly to business necessities and to business opportunities.

There was a time when people discussed the merits of state and private ownership of railways as a question of theory, some being heated partisans of the one system and others equally hot partisans of the other. That time is now past. It is universally recognized among experts that a well managed state road and a well managed private road will adopt nearly the same policy. A large private railway system cannot permanently try to get very much more than a fair rate on its investment. A state railway system cannot, in justice to the taxpayers, afford to get very much less. For state roads have cost money which has been borrowed. The interest on the bonds must be paid, and these interest payments are usually quite as large as the dividends of countries which have private railways. Again, well managed state railways must adopt substantially the same principles of classification and distance gradation as private roads, because it has been proved that only by the adoption of these principles can the railways do the maximum service to the community at the lowest average rates. The chief difference between state railways and private railways

is not in what they can do if they are well managed, but in the particular directions in which they are likely to err if badly managed. With private roads these errors will take the form of fraudulent issue of securities in connection with their capital and of favors to large concerns in their operation. With state roads they will take the form of wasteful and ill-judged expenditures for building and of lack of readiness to take advantage of new methods of operation. It is a somewhat interesting fact that if we take similar roads in different countries the inflation of the capital account due to water in stock of private corporations is just about balanced by the waste due to ineffectiveness of government contract work for public ones.

Though the abuses are different, the remedies are nearly the same in the two cases. Whether a road be operated by a private corporation or a public one, the first desideratum for good management is publicity in all its affairs—straightforward and simple accounting, open bidding with regard to contracts, adherence to the published rate sheets, promotion by merit and not by favor. If to this publicity of method is added responsibility to an independent judiciary, we attain a really salutary system of railway control, whatever the form of ownership or operation. It will be impossible for any railway managed under such a system to make its rates much higher than the rates of other parts of the same country, or even of other countries under similar conditions; because producers of different countries are competing in common markets. If Russian producers and American producers are competing in Liverpool, the charge from the Mississippi River to Liverpool influences the general schedule of transportation rates from the Volga to Liverpool, and *vice versa*. If we can secure fair treatment as between individual shippers, we can usually let the general schedule of rates take care of itself. We can let the agent adopt the system of charging what the traffic will bear if we insist that he does not make this an excuse for charging the individual what his traffic will not bear. For with a system of publicity of rates and responsibility of agents, it will be so obviously disadvantageous to the traffic of a railway itself to have an unreasonably high schedule of charges that enlightened self-interest will dictate the adoption of a tax system which will be more concerned to develop traffic, whether of freight or passengers, than to impose an unnecessary burden upon it.

ARTHUR T. HADLEY,
President Yale University.

Railway (Electric) Economics. No single industry or art has probably ever, within an equal period of time, brought about as great changes in the activities of municipal life as has been the result of the development of the electric railway since 1890. Until about 1900 the development has been essentially that of street surface railways, operating on tracks laid in the street of centres of population, or upon public highways. On account of the use of the highways simultaneously by other forms of traffic, the schedule speed of railways where tracks occupy public highways is necessarily relatively slow (between 9 and 15 miles per hour). It is this speed limitation which has been the cause of the halt in the extension of electric railways, built upon

RAILWAY (ELECTRIC) ECONOMICS

public highways, into the suburbs. At first, too much was expected of these railways, with the result that population centres sprang up at points considerably distant from the cities. The incentives for this migration from the cities were the lower rents, lower cost of living, and, in general, better sanitary conditions of the outlying districts. Of recent years, there has been a very considerable return of the outlying populations to the cities, necessitated by the considerable and prohibitive time interval involved in passing between the suburban homes and the places of business, in the use of the existing suburban electric railways. Generally speaking, the suburban service of steam railroads has not supplied the

known causes, is making imperative the population of the outlying districts, which can only occur with the advent and development of adequate methods of transportation.

Since 1900 the development of high-speed electric railways has been progressing with marvelous rapidity. The best of these newcomers adopt the highest class of steam railway practice in the construction of their permanent way. The essential characteristics of the coming interurban electric railways must be: (1) Safety to the public; (2) high schedule speed; (3) reliability of operation; (4) minimum cost of operation and maintenance.

None of the foregoing conditions can be satis-

PLATE I.

existing want, on account of high fares, time-table limitations, and other aggravations.

The time has come when distance, especially in and about large population centres, is measured essentially and only by the time consumed. A man no longer lives 20 miles or 30 or 40 miles from his office, but he lives 30 minutes or 40 minutes, or one hour distant from his office. In other words, the time has come when the space interval, or distance, between two points or localities, such as two cities or towns, or the home and the office, has resolved itself entirely into a question of time consumed in passing from one point to the other, rather than any question of distance covered. Again, the constantly increasing costs of living in the large cities, due to well-

factorily attained where the cars are operated upon or along public highways upon which pedestrian and vehicular traffic also exists.

Individual or private rights of way are the solution of the problem. The private right of way, however, should be an *individual* roadway throughout, that is, it should be free from grade crossings of all kinds, except at such special points and places where the cars run onto other tracks over which they are to operate.

Interurban roads, to be successful, must be capable of making high speeds, safely and continuously, and this cannot be accomplished where the roadway occupies the public highway or crosses intersecting highways at grade.

Furthermore, when a railway owns its right

of way it is once and for all exempt from the demands, and continuously increasing impositions of public officials in the matter of annual payments to the local authorities as "compensation" for the use of the highways and of repairs to the space between its outside rails, and for various and constantly increasing distances beyond the outside rails. In such matters it has become the practice of some public officials to impose additional burdens every time a given railroad seeks any additional or other privileges in the matter of extensions, track facilities, etc.

In several existing cases interurban lines have been laid on public highways for considerable distances, when they could have purchased rights of way parallel to the highways upon which they have laid their rails, and but a few hundred feet from such highways, for merely nominal sums ranging between \$1,200 to \$2,000 a mile. For a road 30 miles in length, a private right of way costing as much as \$3,000 per mile will increase the cost but \$90,000 for the right of way and (allowing the maximum of three crossings per mile at an average cost of \$5,000 each) about \$150,000 for the crossings, or a total of \$240,000. At 5 per cent the interest on this cost is but \$12,000 per annum. As the items of operation and maintenance must be less for the road using a private right of way, they can safely be left out.

Consider the relative marked advantages which a private right of way 200 to 500 feet from the main road would secure. In the first place a schedule speed three or four times as great could safely be made, and as relatively high speeds and large daily car mileage per car are necessary to secure the best commercial results, for long haul business, this is all-important. In the second place the railway would be free from the petty annoyances, impositions, and demands of ignorant, unjust, or corrupt local authorities. In the third place its property must become more valuable each year as the adjoining territory builds up and settles, and within a comparatively short time it will probably have a railway through a thickly settled community, upon its own property or right of way, subject to no annoyances, impositions, or charges, except the universal and open real estate tax. In the fourth place it will be in a position to so manipulate and increase its schedules as to enable it to "get all there is out of the territory," and it can also arrange for and take care of any passenger or freight business of any existing or future connecting road or roads. In the case assumed in the preceding paragraph, the additional annual fixed charge for these advantages is \$12,000, plus the annual real estate tax against which must be placed, for the care of a good road upon a public highway, the interest on the first cost of paving between the rails and for the required distance outside of the rails, plus the annual cost of maintaining the roadway as demanded by the local authorities to facilitate vehicular traffic, and it should not be forgotten that the cost of maintaining any roadway subject to vehicular traffic is always in excess of maintenance costs where vehicular traffic does not occur on the railway roadway. Consequently for the case of a railway whose tracks are upon a public highway we have two additional costs which are: (1) That of maintaining a paved or macadamized roadway for vehicular traffic. (2) That extra cost of maintaining a roadway, such as cost of

surfacing, alignment, etc., due to the additional use of the roadway by all kinds of vehicles. To the foregoing debits against the tracks upon public highways must generally be added the annual payment exacted for the use of the highway known as "compensation." In several instances which I have investigated the two accounts were about equal, leaving no doubt as to which scheme to adopt, as in the one case the company would have nothing for its money, while in the other it would have had a real estate asset which would constantly increase in value. In addition there would be eliminated the uncertain, constantly increasing, and constantly more serious claims on account of accidents, due to collisions, etc., on account of the development of the territory and the constantly increasing use of the railroad by the public together with consequent greater use of the highways by the public.

The foregoing has reference especially to the physical details of the permanent way of the highest type of the coming high speed electric railroads which will play such an important part, not only in the imminent necessary readjustment and distribution of congested populations, but in the future economic processes and development as well. At present and for a while the coming high-speed general traffic, interurban and suburban electric railways will be, in most cases, passenger transportation enterprises. That such systems are, however, destined to be important factors in the transportation of goods and merchandise admits of no doubt whatever.

The freight and express traffic of existing interurban electric roads has been shown by the experience of the interurban lines in the United States and elsewhere, to be a profitable portion of their business and one which bids fair to develop enormously. It is difficult yet to obtain any satisfactory figures as to just what this business will amount to, but from the information available from the roads investigated, a fair present average on a good road shows that it is now from \$500 to \$1,000 per annum per mile of single track, depending upon local conditions and the extent to which the freight and express business has been sought and developed. There is no doubt but that the same reason which has developed the passenger business on electric lines, that is, short headway, will be and is a large factor in developing the freight and express business. With steam railways the object is to make every freight train unit a self-supporting or paying unit, which is also, as is well known, the process sought to be followed by steam roads in their passenger business. Steam railway operating economy now lies in the direction of long trains, or in other words, in long headways, and the tendency of modern steam railway economy is toward building larger and heavier freight engines, and cutting down grades and eliminating curves so as to reduce the cost of the "ton-mile," etc.

In the case of electric roads the unit at present is not the ton-mile, but the car-mile, and there is practically no economy to be gained by running long trains. It has been demonstrated that passengers can be profitably carried for less per mile on interurban roads paralleling steam roads than the steam roads have been able to carry such passengers for. This condition is due to the fact that electric roads operate single cars or trains at frequent intervals, and increase the

RAILWAY (ELECTRIC) ECONOMICS

"riding habit." The same law holds good in freight transportation. If the commercial interests of a community realized that they could replenish their stocks upon a day's notice, they would cease laying in supplies of goods of such quantity that would last them a week or ten days, or possibly two weeks, as is now the case, and through the saving thus secured in insurance, interest, warehouse handling, etc., could afford and would pay a higher rate to the electric road for the "express" handling of goods than that now paid to steam railway companies. In other words, a rapid and frequent train service, such as electric roads can give, will not only materially increase the freight and express business, but by eliminating the economically non-productive conditions now existing between the producers and the consumers will develop a most important landmark in political economy.

It is an unfortunate fact that engineers and others who have had to do with heavy duty and high-speed electric traction enterprises have not at all appreciated the economic relations maintaining between various relatively high schedule speeds and the costs of establishing and maintaining such schedules. The proof of this ignorance of the costs of high schedule speeds is to be found in the numerous general specifications for high speed electric railways wherein are to be found the provision that:

The schedule speed of the train units shall be miles per hour, allowing seconds for stops at stations, averaging miles apart.

While it is true that high-speed railways are now economic imperatives in and around large commercial centres of population, it should never be forgotten that very high schedule speeds with frequent stops are expensive, and, therefore, only warranted in special cases. The schedule speed

and therefrom a set of approximate conditions selected upon which to base the determination of an accurate set of speed-time and energy curves in the construction of which is considered and represented and determined the influence of all the details of alignment, gradients, and stops of the line as surveyed.

Two or three *actual* and *accurate* total run sheets, for runs in both directions between termini, should be constructed before attempting to arrive at a conclusion as to the most economic schedule to adopt. Plates I, II, and III show examples of sections of actual total runs or individual runs, between two stations, of such accurate determinations, made in connection with the development of the engineering details of the New York & Port Chester Railroad. Such curves also give valuable information relating to the proper gearing of any given equipment for the work it will be called upon to do. Generally speaking, it will be found that motors should be geared for the lowest maximum speed, allowing a fair margin for occasional required increases due to the necessity of making up lost time, for the making of the required schedule. A gear ratio giving an unnecessarily high speed not only overheats the motors, but produces unnecessarily great demands upon the transmission system and the generating and sub-stations.

In determining upon a schedule, not only must the matter of motor heating be considered as affected by different rates of acceleration, but there must also be considered and determined the matters of the line fluctuations together with those of energy, input and station loads. While rapid accelerations effect marked energy savings, it is entirely possible to wipe out any advantage so obtained on account of the poorer boiler, engine, and generator economies due to irregular load curves and low power factors.

TABLE I.

| Distance between stops | | Watt hours per ton mile for schedule speeds of | | | | | |
|----------------------------------|--------|--|------------------|------------------|------------------|------------------|------------------|
| Miles | Feet | 40 miles per hr. | 35 miles per hr. | 30 miles per hr. | 25 miles per hr. | 20 miles per hr. | 15 miles per hr. |
| 3 | 15,840 | 110 | 80 | 78 | 65 | 53 | 40 |
| 2½ | 13,200 | 121 | 90 | 83 | 74 | 54 | 40 |
| 2 | 10,560 | 142 | 99 | 86 | 80 | 60 | 41 |
| 1½ | 7,920 | | 123 | 95 | 85 | 68 | 43 |
| 1 | 5,280 | | | 128 | 90 | 74 | 50 |
| ½ | 2,640 | | | | 145 | 119 | 56 |
| ¼ | 1,320 | | | | | | 120 |
| Train friction in pounds per ton | | 35 | 30 | 27.5 | 25 | 20 | 15 |

affects not only the cost of the motor equipment, but also that of the main generating station, transmission system, and other details. For this reason the matter of the proper schedule speed should always be carefully and exhaustively investigated and determined before it is announced. The scientific method of procedure consists in first making a rough preliminary determination by assuming the line to be straight and level and the stations or stops at equal distances apart. By assuming certain safe and practically standard data, such as tractive effort, braking effort, time of stops, and train friction, and having the distance between stations, a set of roughly approximated speed time, distance time, and energy curves, can be calculated and therefrom approximations obtained of the energy which will be required to maintain various resulting schedules,

The braking effort or retardation is taken at 150 pounds per ton.

The stops are taken at 15 seconds each, except in the case of the 15-mile per hour schedule, where 10 seconds is taken.

The foregoing figures are for cases of approximately level and approximately straight roads.

For a schedule of 40 miles per hour the speed attained will be between 60 and 65 miles per hour. A schedule of 25 miles will require speeds of from 40 to 50 miles per hour, etc.

The rate of acceleration for the long runs varies from 75 to 110 pounds per ton, going as high as 210 pounds per ton for short runs.

The foregoing applies to single car units. If units of more than one car be used, the friction in pounds per ton will decrease and with it will also decrease the energy consumption in watt hours per ton mile.

Some of the places have been left blank on account of the impracticability, with existing apparatus, of making some of the high schedules with the short distances between stops assumed in the table.

The figures are for the energy required at the motors.

RAILWAY (ELECTRIC) ECONOMICS

Table I shows, strikingly, the relations existing between schedule speed, stops per mile, and corresponding energy consumption. In the face of the conditions shown in the table it is difficult to imagine why the matter of schedule speeds has been handled so recklessly by engineers and promoters inaugurating new enterprises.

In view of the rapidly increasing maximum speeds at which interurban systems are being operated, attention must also be paid to those details of design which will reduce the train resistance and more especially that element thereof known as "wind resistance," which is by far the greatest component of train resistance. Smooth, flat sides with the platform ends rounded or tapered and enclosed are among the simple and effective methods of car construction employed. It is astonishing what a saving in

than 55 such formulæ. A complete list would doubtless include twice that number. These formulæ differ greatly in their form and in the purpose for which they are intended. In some cases, the formula is intended to give the total resistance, including that of the locomotive and the cars constituting the train. In other cases the formula gives only the resistance of the train. In some cases the formula takes into account only the velocity of the train; in other cases the formula takes into account the number of cars, and the weight and the length of the cars in the train.

It is apparent that the matter of schedule speeds, as related to costs of operation, is not generally understood.

The schedule speed may be a large factor in determining the commercial success or failure of

Actual comparative run curves showing economic results of different schedule speeds. Compare table at right.

watt-hours per ton mile or per car mile and consequently, in cost of operation, the application of the simple methods above suggested will produce as indicated by recent tests.

The problem of determining the total amount of mechanical resistance opposed to the motion of a car or train is a very difficult one, for which it may be said, in fact, that no general solution applicable to all cases has thus far been found. It has been generally admitted, for a long time, that this resistance, to which the general term "train resistance" has been applied, varies with the speed of a car or train; but there is a wide difference of opinion in regard to the amount of variation to be expected at different speeds. Many "formulæ" for calculating the train resistance as a function of the speed have been proposed and used. J. A. F. Aspinall, in his paper on 'Train Resistance,' read before the Institution of Civil Engineers, in 1901, tabulated no less

an enterprise. As an illustration see Table I) we see that the watt-hours per ton-mile, allowing a stop every two miles, required for a 40-mile per hour schedule, are 142, while for a 35-mile per hour schedule there are required about 99 watt-hours per ton-mile. We assume, as an average, a road 30 miles long, over which are made 100 round trips per day, with cars weighing 45 tons each, and assuming a loss of 25 per cent between the motors and the main power station switchboard, and taking the cost of energy at \$.006 per kilowatt hour we have

$$100 \times 30 \times 2 \times 45 \times 0.006 \times 365 \times 142 = \$111,952.80$$

$$0.75 \times 1000$$

as the cost of operating the 40-mile per hour schedule with single units and

$$100 \times 30 \times 2 \times 45 \times 0.006 \times 365 \times 99 = \$78,051.60$$

$$0.75 \times 1000$$

RAILWAY (ELECTRIC) ECONOMICS

as the cost of operating the 35-mile per hour schedule with single units.

The difference between these costs is \$33,901.20, which, at 5 per cent, is the annual interest on \$678,024. For a road 30 miles in length, the time between termini for the 35-mile schedule would be 51.4 minutes, while the time for the 40-mile schedule would be 45 minutes; a difference per trip of 6.4 minutes. The matter is also well brought out in the "run curves" shown in plates I, II, and III.

Earnings.—One of the most serious and inexcusable mistakes is that of computing or determining the probable gross income of a proposed new railway enterprise by the application of general average data to a specific case. The proper determination of the probable gross earnings for each or any case requires specific determinations and studies of the territory considered which will show: (1) Estimate and money value of probable passenger business between each of the centres of population and the principal terminus or termini, if both be important places. (2) Estimate and money value of probable passenger business between each of the centres of population between the termini and each of the remainder of such centres of population. (3) Estimate and money value of the probable annual excursion or recreation passenger business. (4) Estimate and money value of the probable express and freight business. (5) Rates of fare which are proposed to be charged. Should an existing road or roads be occupying the territory proposed to be served, the relation between existing rates of fare and the proposed rates is of course an important factor in this latter consideration.

As a matter of fact, instances of totally unoccupied territory are very rare. Trolley roads are almost certain to be in operation and, generally, in instances of most promise, steam roads will be found serving the territory after a fashion. A knowledge of the business of the existing railways operating in the proposed territory is generally of value and should be ascertained. For steam roads this can be readily done by purchasing one ticket, at each station within the territory to be served, to every other station on a certain day of the month, and then repeating the purchases at given intervals, say 10 days apart for some months. As each ticket has a serial number the existing local and through passenger business for any territory can be readily determined by noting the serial numbers and subtracting the numbers on those first purchased from those last purchased. This method will also show the variations of the passenger traffic.

The business of the surface trolley roads can be determined by stationing men at predetermined important places along the routes and noting the car number, time of day and number of passengers on each car as it passes a given point. For this work some experience is necessary to estimate the number of passengers on the car as it passes the observer. It is remarkable how accurate a little experience and care will make such observations. The difference in the number of passengers on a car as shown by the observations of the consecutive observers will show, approximately, the amount of local business or business between centres of population. These observations will also show, approximately, the total

trolley passenger business for the territory and will provide data from and for the actual case in hand, from which can be determined the rides per capita between the different centres of population. It is needless to say that the detailed data above noted will not be supplied by the existing operating railways, whence the necessity for the relatively large expenditure of the time and money to secure them. Should the proposed railway be one of great magnitude which will involve the expenditure of large sums for its installation, it is best to extend the observations over both the summer and winter months, as by so doing a more reliable average will be obtained.

Having now the approximate actual existing traffic business between each of the towns and the termini, as well as the local traffic between each of the towns, an estimate is made of the probable increase of traffic due to the increased facilities. Upon three branches of the New York, New Haven & Hartford Railroad which were changed from steam to electric systems, the following results were obtained:

COMPARISON OF PASSENGERS CARRIED PER ANNUM UPON CHANGING FROM STEAM TO ELECTRIC OPERATION.

| Name of road | Passengers carried per annum operating by | |
|------------------------|---|-------------|
| | Steam | Electricity |
| Nantasket branch..... | 304,292 | 702,419 |
| Highland division..... | 387,695 | 1,060,617 |
| New Canaan branch.... | 98,302 | 184,728 |

The systems cited, at the time these results were obtained, operated on hourly and half-hourly schedules. The differences would undoubtedly be much greater with shorter headways; these figures, however, show nearly 100 per cent increase as a minimum and about 270 per cent increase as a maximum.

An estimate should now be made of the passenger traffic which will come to the new road. Let there be seven towns, as A, B, C, D, E, F, and G, including the termini. Determine upon the average fares between each place, and let A', B', C', D', E', F', and G' be the respective populations of which A is the main or principal terminus. Let the estimated rides per capita from G to A equal N rides per annum, and the rate of fare between A and G equal R, then $G' \times N \times R = S$, which is the revenue which will accrue on account of the community of interest between G, the minor terminus, and A, the principal terminus. Proceeding in this manner for each town or population centre, we obtain the total estimated revenue. As a concrete instance will be more impressive, attention is directed to Tables II and III showing computations of this kind worked out by the writer.

earnings per capita taken from interurban statistics, which data were, however, not used until the existing railway earnings per capita for the case in hand had been determined by ascertaining the existing business. The railway earnings of places relatively remote from a large city are generally greater per capita for interurban railroads than those of the nearer places.

The above estimates of the earnings were made after a careful study of existing conditions, as well as of the nearest existing approximations, in the territory to be served by the New York &

RAILWAY (ELECTRIC) ECONOMICS

Port Chester Railroad. These investigations covered many months and had for their objects:

1. A careful study, after personal observation, of the habits of the people along the line; that is, ascertaining how, when, and where they traveled.
2. The existing inducements which would cause people to travel between the various cities and towns.
3. Ascertaining the occupations of the people and the probable stability of their employment.
4. Examination of the national censuses, as well as of the various ward, precinct, and school censuses.
5. Personal observations at the various points at which the public boarded trolley cars, at all hours of the day and night for many months, to count and ascertain the amount and division of the existing travel.

results given in Table II. Both methods can be used and should be in all cases of this kind where a careful study of the question of probable traffic is important. The figures obtained differ slightly from those reached on the population basis, but approximate so closely as to afford a satisfactory check.

In arriving at the probable earnings per capita, per annum (Table III), a careful study was made of the average railway fare expenditures per capita as they now exist in this territory, that is, the approximate amounts of money paid to the existing steam and trolley roads by the

TABLE II.—ESTIMATES OF EARNINGS ON POPULATION BASIS.

| Between | Population carried per year | Average fare per trip | Annual income |
|--|--------------------------------|--------------------------|---------------|
| Port Chester and New York..... | 7,000 x 120 | 15 cents | \$126,000 |
| Harrison, Rye and New York..... | 2,000 x 120 | 15 " | 36,000 |
| Mamaroneck and New York..... | 5,000 x 120 | 12 " | 72,000 |
| New Rochelle, Larchmont and New York..... | 20,000 x 150 | 10 " | 300,000 |
| New Rochelle and Port Chester..... | 30,000 x 60 | 5 " | 90,000 |
| Mount Vernon, Pelham and New York..... | 28,000 x 150 | 6 " | 252,000 |
| New Rochelle and Mount Vernon..... | 35,000 x 30 | 5 " | 52,500 |
| Mount Vernon and Port Chester..... | 62,000 x 20 | 7 " | 86,800 |
| Bronx and Mount Vernon..... | 100,000 x 50 | 5 " | 250,000 |
| Annual summer and recreation business of the road... | 1,500,000 | 15 " | 225,000 |
| Total passenger income per year..... | | | \$1,490,300 |

A careful study of the business of the existing trolley and elevated roads and steam railroads operating in the district was made, as well as of the nearest existing approximations now operating elsewhere, and all data thus obtained were plotted, and therefrom the deductions here shown were drawn. It was found that this estimate contemplates carrying the population served approximately 100 times per year. The business will include 18,000,000 fares per annum. As these 18,000,000 fares are based upon approximately 4,500,000 car miles, it will be seen that there must be carried but four passengers per car mile; 18,000,000 divided by 365 = 49,300 passengers per day of 398 trips, or an average of 124 passengers per complete trip of about 22 miles. There are 22 local stations and 12 express stations, which would give, on an average, 6 passengers per station per trip for the local service, and 10 passengers per station per trip for the express service.

TABLE III.—ESTIMATES OF EARNINGS ON PER CAPITA BASIS BY DIVIDING TERRITORY INTO ZONES.

| Between | Popula- tion | Earn- ings per capita | Total |
|---|-----------------|-----------------------------|-------------|
| Port Chester and New York | 8,000 | \$15.00 | \$120,000 |
| Harrison, Rye and New York | 2,000 | 15.00 | 30,000 |
| Mamaroneck and New York | 5,000 | 15.00 | 75,000 |
| New Rochelle, Larchmont and New York..... | 20,000 | 12.00 | 240,000 |
| Mount Vernon, Pelham and New York..... | 30,000 | 10.00 | 300,000 |
| New Rochelle and Port Chester..... | 30,000 | 3.00 | 90,000 |
| New Rochelle and Mount Vernon..... | 45,000 | 3.00 | 125,000 |
| Mount Vernon and Port Chester..... | 80,000 | 1.50 | 120,000 |
| Port Chester, Bronx and Mount Vernon..... | 100,000 | 3.00 | \$300,000 |
| Total..... | | | \$1,410,000 |

Table III was worked out upon the zone system and for the purposes of checking the

residents of the different zones into which the district was divided for this purpose. In following out this method, 132d Street and Willis Avenue of New York city was taken as the centre, and circles with 132d Street and Willis Avenue as a centre were drawn, the radius of each circle being one mile greater than the other. In this way 25 circles were obtained. Had the circles simply been carried to the State line, but 24 would have been obtained. Inasmuch, however, as there is quite an extensive population immediately beyond Port Chester, Conn., all of which will have easy access to this road by using the existing trolley roads for a short distance, the Connecticut population was taken into account for a distance of three miles from what would be the end of this road. The population for one half of a mile on each side of this railway was obtained for each of the zones, that is, the distance between any two consecutive circles, and the riding data of this population determined. For the purpose of arriving at this information, a careful count during the summer and winter was made for a period extending over six months, of the number of passengers on the trolley cars at different points in this territory, as well as the number of people using the steam road at each of the stations in the territory under consideration. This information was obtained in the way already described.

When it had been obtained, a series of curves were plotted, showing the relations between receipts per capita and population served for different periods, and localities or zones. From the curves so determined, the figures for the receipts per capita given in this statement were summarized. Of course the estimated earnings per capita given in this summary are less than the results actually obtained, as the figures given are those estimated for the New York & Port Chester Railroad portion of the business only.

Table IV shows some of the results which now obtain upon a number of systems operating in and about various large cities of the United States. They are all city railway systems, and

RAILWAY (ELECTRIC) ECONOMICS

TABLE IV.—STATISTICS OF LARGE CITY PROPERTIES.

| | Miles of track | Population | Gross receipts | Gross receipts per mile of track | Gross receipts per capita |

a. Local estimate of city and suburb, 1903.

b. Local estimate, 1901.

with the exception of the Interurban Street Railway Company of New York, all trolley roads. In most cases, the figures for traffic are for the fiscal year 1902, while the population, unless otherwise indicated, is for 1900. The population given is that of the city in which each company operates. The column of gross receipts gives the entire receipts from passengers of the respective companies, including the receipts from branches extending outside of the city limits, so that the "gross receipts per capita" are in some cases slightly higher than they would be if they showed the receipts of the actual population served. The Brooklyn and Boston figures include the receipts from the elevated lines in those cities, as these systems in each case are operated in conjunction with the surface systems, and their receipts cannot be separated. Where there are two or more companies in the same city the "gross receipts per capita" show the gross receipts of all of the surface street railways in the city.

In cases where there are no existing steam railways serving the population to be connected by the electric lines it is advisable to count the traffic by vehicles and stages between the different centres of population for periods sufficiently long and at proper intervals to give a fair annual average. From this information and by comparison with the traffic of existing roads in similar conditions a fairly satisfactory estimate can be secured. In such comparisons the "population served" may very properly be considered to be that residing within about 1½ miles on each side of the proposed line, in cases, of course, where there is no other railway serving them. The entire population of large terminal cities should not be added to the total sought, as all the residents of such city will not be probable patrons of the railway. In making per capita comparisons of this kind between a proposed and an existing railway it is often better, where both have a large terminal city, to leave this city out of account in both instances. An even better plan, where the riding between stations on the operating road is known, is to make the comparison on the zone system, as already described.

Thus far the method which should be followed in determining the probable gross passenger earnings only of any interurban system has been described. The matter of determining

the gross passenger earnings has been gone into somewhat in detail, for the reason that upon roads of this character the passenger earnings at present are by far the greater portion of the total gross earnings.

In addition to passenger earnings, however, estimates should be made of the probable gross revenue which will be derived from the carrying of freight, express, and mail. The data now available on this subject are not very complete on account of the fact that this branch of the interurban business has not yet been developed and systematized sufficiently to be able to furnish accurate data. For any special case, however, the gross freight and express business can be worked out and determined by a process very similar to that used in determining the gross passenger revenue. The process consists, first, in ascertaining the amount of freight and express business coming into and going out by railway of each of the centres of population (in cases where an existing steamroad is doing this business), and then determining what proportion could be secured by the electric road. Should there be no existing steam railway, the method of procedure would be to ascertain the total production and consumption of the territory proposed to be served, which would include, of course, products of all kinds, that is, agricultural products and mining and manufacturing products. An estimate of the gross tonnage from every point along the line of the proposed road can then be made to the points at which the freight would probably be carried, such as some large city or some other connecting road.

In estimating freight traffic for towns where there is no existing road supplying the population, and, consequently, where no actual approximate railway data can be obtained for the probable ingoing and outgoing freight receipts of any single or number of population centres, another way to proceed is to ascertain the population of each of the population centres, and then have recourse to statistical data published by the United States and other governments, showing consumption and production per capita for given localities. From such data, an estimate can be made of the probable railway tonnage for the proposed road. Such an estimate will, of course, show the tonnage which would accrue on account of a service, such as is now

RAILWAY (ELECTRIC) ECONOMICS

in existence around the country, that is, the ordinary steam railway service. There is no doubt, however, but that the actual tonnage for an electric service operating frequent units would be greater than that enjoyed by existing steam roads. Instances often exist where freight and goods are taken out and into a community by means of wagons plying to and from railway centres distant anywhere from 5 to 10 miles from the community. Where such cases exist fairly accurate data can be obtained by ascertaining the business which is done by such wagon service.

There is no doubt that such relatively high-speed, high-class interurban electric railway systems which are here being considered and which are to play an important if not revolutionary part in transportation economics,

mile of single track per year from freight and express, and this in cases where the whole or the major part of the tracks are on public highways, and where, consequently, the schedules are limited to 16 or 20 miles per hour, which is a perpetual handicap to interurban high-speed railways so designed and installed.

Expenses.—In connection with electric railway operation, an unfortunate habit has developed of estimating the annual costs of operation and maintenance as a percentage of the gross receipts. Estimates of this kind really mean nothing and have no real value even for comparisons. They are even dangerous when used in such computations and determinations as discussed here, on account of the difference in conditions, such as number of cars operated, length of route, headway, average distance each

Comparative run curves determined for an actual case showing economic results of different schedule speeds. See and compare table in centre.

will soon attain gross passenger earnings of from \$12,000 to \$15,000 per mile of single track per year and more, and will also attain additional earnings from freight, express, and mail business of from \$2,000 to \$3,000 per mile of single track per year. This refers especially to roads operating at schedule speeds of from 30 to 40 miles per hour and more, on private rights of way, connecting large centres of population and having stations or stops from a quarter of a mile to a mile or more apart, running cars at frequent headway, and when designed and installed by competent railway experts, fitted by experience to judge of the present and future economic activities of given conditions. Already some of the better classes of electric interurban roads are obtaining \$10,000 to \$12,000 per mile of single track per year from passengers, and \$1,000 to \$1,200 per

passenger is carried, and tributary population per mile of track, and especially relative receipts, etc. In order to use the percentage of the gross receipts method in making comparisons, some of the details of operation should accompany the statement of the percentage of gross receipts required to operate the road. Such accompanying details should show: (1) The gross receipts. (2) The car mileage operated daily and yearly. (3) The average daily mileage per car. (4) The total number of miles of single track operated. (5) The amounts annually expended for maintenance of way and structures, and maintenance of equipment, and the amounts per car mile for these items. (6) The physical condition of the property. (7) The capital liabilities and fixed charges. (8) Traffic density or passengers carried per car mile.

Of two roads having approximately the same

RAILWAY (ELECTRIC) ECONOMICS

amount of track, the one operating at the larger percentage of the gross receipts may have the larger net. Suppose one of two such roads to have gross receipts of \$1,500,000, and to be operating at 60 per cent of its gross receipts. Suppose the second of the two to have gross receipts of \$900,000, and to be operating at 50 per cent of its gross receipts. In the first case, the net will be \$900,000, while in the second case it will be but \$450,000. If each has approximately the same amount of track, the fixed charges will probably be nearly the same. This instance will show the necessity for additional detail if such data are used.

The only safe way to proceed is to determine the detail cost of each item entering into the total cost of operation. The subject is generally divided into four subdivisions by existing steam and some electric systems, as follows: (1) Cost of maintenance of roadway and structures. (2) Cost of maintenance of equipment. (3) Cost of conducting transportation. (4) General expense.

Any item of operating costs can be classified under one of the four heads above given. It is more satisfactory to use the following subdivision for electric systems:

1. Cost of train crews.
2. Cost of station men, such as ticket agents, etc.
3. Maintenance and inspection of cars and equipment.
4. Maintenance of roadway and structures.
5. Cost of operating main power station, including fuel, oil waste, etc., and labor and repairs.
6. Cost of operating rotary stations.
7. Salaries of officers and clerks, etc.

TABLE V.—APPROXIMATE COSTS PER MILE OF SINGLE TRACK.

| Items | Maximum | Minimum |
|--|---|---|
| Rails, 80 lb. T (\$33 per ton delivered, including splice plates, bolts, spikes, and drilling) | \$5,100.00 | \$4,460.00 |
| Cost of labor for handling and laying | 900.00 | 900.00 |
| Track bonding | 1,750.00 | 1,400.00 |
| Ties, 6 x 8 x 8, at 70 cents each | 1,848.00 (2-foot centres) | 1,474.00 (30-inch centres) |
| Rock ballast, 10 inches deep, 11 feet wide, and carried to top of tie | 4,125.00 | 2,062.50 |
| Gravitation | 6,000.00 (Crushed stone \$1.50 per yard) (20,000 cubic yards per mile of track) | 1,800.00 (Crushed stone, 75c. per yard) (10,000 cu. yds. per mile of track) |
| Third rail | 7,000.00 | 3,400.00 |
| Copper or other electrical conductors, and installation thereof | 2,500.00 | 1,500.00 |
| Bridges and culverts | 12,000.00 | 4,000.00 |
| Labor and incidentals | 400.00 | 200.00 |
| EQUIPMENT | | |
| Rolling stock, motors, and equipment from \$10,000 to \$5,000 per car | 8,000.00 (At five minute headway) | 1,000.00 (At one hour headway) |
| Power-stations at \$100 per kilowatt, substations at \$40 per kilowatt, etc. | 18,000.00 | 4,000.00 |
| Incidentals, including block-signal system, telephone and telegraph, fencing, etc. | 4,000.00 | 1,000.00 |
| Real estate for right of way | 20,000.00 | 1,600.00 |
| Total | \$90,623.00 | \$27,796.50 |

Each factor of each of the foregoing items should be carefully computed and the total cost of operation and maintenance thus ascertained. This is the only safe and true way of arriving at a proper conclusion.

The fixed charges include the following items: (1) Interest on bonds or other interest-carrying obligations. (2) Cost of leaseholds or rentals. (3) State and other taxes. Taxes are often placed under the head of operating expenses. They are sometimes determined as a percentage (from 2 to 5 per cent) of the gross receipts. Space will not permit an extended discussion of the details of the computations of the costs of construction and equipment. Table V. will give data from which such costs can be determined. In each instance, however, every item of the cost of construction and equipment must be computed and determined.

Equipment.—Among the most important and trying economic questions relating to the design, construction, and operation of high-speed electric railways reaching well out of the congested centres of population, which the designing and managing engineers are called upon to decide, are those relating to the character of construction and equipment to be adopted, and the character and kind of service to be given. These considerations may be stated as follows: (1) Number of tracks to be installed. (2) Speed, headway, and size of the train units. (3) Weight of rails and characteristics as affecting costs, of ties, ballast, block signal system, and other details of permanent way. (4) Character of rolling stock and power stations and transmission system, together with the location, design and number and character of the passenger stations.

All of the foregoing are functions of the estimated gross earnings of the proposed installation. The earnings must be taken as the starting point. At the present time the plans of some proposed systems appear to indicate a tendency, in some instances, to do too much. There appears to be, in some cases, a lack of appreciation of the proper relations which should maintain between fixed charges and the estimated gross receipts. In some cases, which I have investigated, the fixed charges upon installations, as proposed, equal 40 per cent to 50 per cent of the estimated gross receipts, a margin far too close for safety. For the cases of a number of the higher class steam roads in operation the fixed charges are found to vary between 20 per cent and 30 per cent of their actual receipts. On account of the demonstrated ability of electric systems to develop business more rapidly than their steam predecessors the above ratio of the steam lines may at times be exceeded in such cases where the estimated earnings have been conservatively made by experienced engineers. It is always best, however, to keep on the safe side, and let the earnings, after the proposed system is operating, do something toward augmenting the installation. If this latter course be followed it is safe to say that the officers and stockholders of the company will not have nearly as many sleepless nights as they otherwise may have should they too ambitiously "reach out and lead." In addition, there will probably be less activity in the receivership and absorbing and reorganization businesses.

RAILWAY (ELECTRIC) ECONOMICS

Generally speaking, the idea should be to install no more tracks than can be kept busy safely and satisfactorily, taking care of the business in sight and which apparently will accrue from the first few years of development, on account of the increased or improved facilities proposed to be given. Relatively high speed for these roads must be maintained. Again, in attempting to get as much out of a pair of tracks (single-track roads being out of the question) as possible, it must not be lost sight of that while the capacity of a given installation with a given schedule speed can be increased by gradually adding train units up to a certain point, a limit will be reached, after which, on account of the headway requirements, any increase in the number of units will necessitate a reduction of the schedule speed, and if carried far enough, the carrying capacity will be actually reduced; any material reduction of schedule speed will probably also cause a loss of traffic. If a schedule speed of 30 miles per hour has been determined upon as that which will be required for a given territory, the idea should be to ascertain the maximum capacity of say two tracks for the proposed road when operating at that schedule. If it be ascertained that the two tracks will not be sufficient, at the determined schedule to carry the maximum estimated business, then a third track, to be used for express trains going one way during the morning and the other way in the evening, should be estimated upon. It will generally be found that wherever a third track is warranted the conditions will generally admit of the small additional outlay required for a fourth track. The additional costs are those required for the relatively slight additional graduation (earth and rock-work) and the additional rails, ties, and ballast, and the labor of installation. In cases of supplying the suburbs of such cities as New York, Boston, Paris, London, Berlin, Chicago, and San Francisco, and similar cities, it will generally be a question of determining whether two tracks or four tracks should be installed, and the safe and conservative solution will always be arrived at by considering the comparative ratio of the different fixed charges, which two, three or four tracks will impose to the probable gross receipts, estimating the gross receipts for the conditions which will exist when the road commences operation. In some instances, where a rapid growth and development is apparent, such future development must be allowed for in the original design.

As an illustration of the application of the foregoing principles suppose the estimated gross receipts of a proposed road are \$900,000 per annum. Suppose, furthermore, that a two-track road could be installed to do this business for \$5,000,000, and that a four-track road would cost \$6,000,000. The fixed charges for the two-track road, at 5 per cent, will be \$250,000 per year, while on the same basis, those for the four-track road will be \$300,000. The annual operating expenses, taxes, and insurance would be about \$500,000, for the conditions assumed for the two-track road, leaving for the two-track road \$400,000 for fixed charges, etc. Deducting the \$250,000 fixed charges of the two-track road would leave \$150,000 annually to be applied to unforeseen contingencies, betterments, and other

accounts. If we assume that we will run approximately the same number of train units between the termini daily for the four-track road at the start, the operating costs will be about the same. In order to justify such an assumption it would, of course, be necessary to reduce slightly the schedule of the two-track road, which can at times be done. For the case of the four-track road we will then have left, after deducting say \$525,000 for the annual cost of operation, taxes, and insurance, the sum of \$375,000 for fixed charges, etc. If we now deduct the fixed charges of \$300,000, we have left \$75,000 for unforeseen contingencies, bad times, betterments, and other accounts, a margin which is somewhat too small for the solid comfort of the bondholders and the stockholders, especially that of the stockholders. In fact, an enterprise starting upon its career upon the last basis might well be called a "receiver's delight," a "reorganizer's joy," or a "stockholder's obsequies" installation. A four-track installation for the case we have assumed would only be justified where a great immediate development along the line of the road was apparent. Even then the engineer should prepare statements of both conditions, as above outlined, and submit them to the bankers or underwriters so that they will have full knowledge of the relative conditions and contingencies.

The development of large cities and the consequent apparent exceeding of the capacity limits of some existing rapid transit or urban rapid transit system has offered opportunity for much lay, semi-professional, and even so-called engineering criticism of the shortsightedness of the originators of such transportation systems in not installing more tracks at the time of the original construction. If such critics will investigate they will ascertain that, generally speaking, such roads have been hard pressed for many years to make ends meet, and that they are now only reaping their hard-earned fruits. A little thought will also show that had such systems at the outset provided installations adequate to do the business they are now receiving, they would certainly, in years past, have suffered financial difficulties, to state it mildly. As a general rule promoters and financiers are fairly healthy, and in cases where they are not entirely so there are other and milder means than that of placing large amounts of money in relatively certain jeopardy, by reaching out and leading, of recruiting their exhausted energies.

The very best materials and construction only should be employed for the permanent way and the rolling stock, as it is only by so doing that the maximum safety can be assured to the traveling public, which must always predominate in considering costs of construction. Accidents are always costly, as are also conditions of uncertain operation and delays. The public will not patronize a road upon which accidents are frequent or whereon uncertainty of operation or delay is at all marked. Inferior permanent way and rolling stock is, therefore, equivalent to burning the candle at both ends on account of the natural reduction of receipts, for the reasons stated above, and the additional increase of operating and maintenance costs which maintain on poorly engineered and poorly installed railways.

Regarding the determination of the details of the passenger station. It should never be lost sight of that the location of the passenger stations may have a material influence upon the business which the road will do, depending upon whether the stations are located so as to render them easy of access or otherwise. The matters of the general design, size, finish and specific details of the station will have to be determined separately for each case.

In designing the stations, however, the object should be to provide stations wherein the annual aggregate salaries of ticket sellers and attendants will be a minimum. If ticket offices be placed along each side of the roadway at each station this will not be the case. The stations between the tracks on some elevated systems, known as "island stations," are examples of the minimum operation and maintenance cost idea. About half the annual attendance is required for such stations as compared with those on each side of the tracks. The objection sometimes urged against the "island station" system is that people who are so disposed can ride back and forth any number of times after paying a single fare. In connection with the development of the engineering details, of a railroad designed by the writer in New York State, the tracks of which will be upon a private right of way throughout, and furthermore, upon earth or rock cuts or fills, the writer devised and recommended the following station plan: Wherever the roadway is on an embankment and above the grade of the streets, the station is to be constructed by providing under the roadway and approximately at right angles to the tracks, a passageway or tunnel extending entirely across and under the railway roadway, and 50 feet or more, as may be required, in width. The width of this passageway would, of course, be along the length of the tracks. In the centre of this passageway is to be one ticket office, provided with proper approaches, from each side of the roadway; and inside of and beyond the ticket office are to be waiting-rooms, etc., and the stairs ascending to the island platforms between the tracks. This underground passageway is to be of the concrete-steel construction. Where the tracks are in a cut, at station locations, and consequently beneath the surface of the streets, the design provided for a concrete-steel structure over and entirely across the tracks, wherein is located one ticket office, as before, with waiting-rooms, etc., inside the ticket office, and stairs descending to the island platforms. Stations of this kind are worth about \$8,000 each. It is evident that the same plan can readily be used for a two-track road.

Where a high-speed electric railway crosses a public highway or other railway, either above or below the grade of the other road, the design of such a crossing, especially where it is below, and consists of a subway of greater or less length, may exercise considerable effect upon the subsequent cost of operation of the system, as it may determine the limiting length of the cars where trains are used. The high-speed railways herein discussed should be designed throughout so as to permit of the operation of any of the cars now used by steam railways. There is, however, another reason of essentially

an economic kind. As an illustration, suppose that upon a given road it has been found that on account of the dimensions of part of the subways it will not be possible to use a car more than 40 feet in length, and that train units of three such cars will be required. It is apparent that train units consisting of two 60-foot cars would carry the same number of people as the three 40-foot cars, and allowing one conductor or guard per car, at an operating cost of one man per train unit less. It is easy to see that if train units be operated at frequent headway and for any considerable part of the day, the length of the cars becomes a most important consideration and economic factor of the subsequent costs of operation. Mistakes of the kind have occurred and are now practically the cause of considerable additional fixed costs of operation, which would have been avoided had such apparently small details been given that thorough and competent consideration at the outset which their economic importance demands.

Engineers or experts in making reports often appear to forget or ignore the fact that the essential value of their reports lies in the conclusions, and a brief statement of the bases for these conclusions. The body of a report may contain as much statistical detail and general data as may be required to pad out the document to make its outward appearance justify the fee; but the client, upon receiving the document, will generally search the index for that part of the report giving the conclusions, and the bases therefor. Often the search is in vain.

W. C. GOTSHALL,

President New York & Port Chester Railroad Company.

Railway Engineering, in its broad sense, comprises the work of the civil engineer and the mechanical engineer. The first includes the design, construction, and maintenance of the statical structures, such as the track, bridges, buildings, etc., the second, the design, construction, and maintenance of the motive power, machinery, cars, marine equipment, etc. The term railway engineering is, however, usually used in a limited sense meaning the work of the civil engineer only. It is the purpose of this article to enumerate the general items of work included in railway engineering, and to state briefly the important facts, methods and principles used by the railway engineer in his work. It will be assumed that the reader is familiar with such simple terms as single track, double track, rails, cross-ties, etc., and knows the general form of a railway track in so far as a casual observation reveals it. Bridging, tunneling, and masonry, being covered elsewhere, will not be treated.

Railway Design includes the determination of the general route, and the details of the alignment and gradients of a road, called the location; the determination of the cross sectional form and dimensions of the embankments, excavations, tunnels, ballast, etc.; the determination of the form and dimensions of cross-ties, or sleepers, the form and weight of the rail and its fastenings, the necessary water way to safely pass the water of the various streams and gullies crossed, together with the form and dimensions of the culverts, trestles and bridges; the

design of road crossings, grade, underhead and overhead; the design of docks, warehouses, coaling stations, water-supply works, minor buildings and yards.

Railway Construction is usually performed for the railway company by a contractor. In this case, the railway engineer lays out the work on the ground, measures the quantity of work done, and maintains a general supervision to see that the terms of the contract are complied with. The chief engineer is usually by the terms of the contract the ultimate authority out of court in the interpretation of the provisions of the contract, and he has complete control of the work done under it. When a railway company executes its own work, the engineering department devises the methods of work, secures the necessary tools and machinery, employs and supervises the labor, and in general directs the work, which is done under a superintendent of construction.

Railway Maintenance includes keeping the constructed track in good surface and alignment, from which it is distorted by the action of frost, rain, and the heavy loads going over it; replacing worn out or decayed cross ties; renewing worn out rails; keeping the drainage ditches open, grass and weeds cut, fences in repair, bridges and all other structures in repair; occasional rebuilding of whole structures; laying out and building side tracks and spur tracks to quarries, factories, gravel banks, etc., and maintenance of the water supply works.

Railway Improvement, besides the building of larger and handsomer station buildings, the purchase of larger cars and locomotives, and the improvement of station grounds and roadway, items that appeal to the general observer, includes the far more important but less conspicuous work of reducing the curvature, shortening the line, rearranging the gradients by reduction where possible and adaptation to pusher service where they may not be much reduced, and redistributing the locomotives on the road so that each one may be on that portion to which it is best adapted. This work is usually done under the combined direction of the civil and mechanical engineering departments.

Railway Alignment.—The horizontal plan of the centre line of a railway is a series of straight lines connected by curves. The straight lines are called tangents, because they are tangent to the curves joining them. Formerly these curves were arcs of circles, but they are now almost universally combinations of circular arcs and what are known as easement or transition curves, or spirals. The central portion of the curve joining two tangents is an arc of a circle of some selected radius, and between this central portion and the tangents connected by the curve are two easement curves or spirals, one for each tangent. These curves are not simple arcs of circles, but are curves having a constantly changing radius. Beginning at the tangent with a radius infinitely long, the arc just at this point being practically a straight line, the radius continually decreases, the curve becoming sharper and sharper, till it is reduced to the radius selected for the central portion of the curve at the point where the spiral joins that central portion. An easy transition from tangent to curve is thus secured, and the shock to

the track and passenger greatly reduced or entirely eliminated. The circular curves are known by their degrees, that is, the number of degrees subtended at the centre of the circle by a chord of 100 feet. If a chord of 100 feet subtends 4 degrees at the centre of the circle, the curve is known as a four degree curve. The radius of a one degree curve is 5729.65 feet, usually assumed as 5730 feet. The radius of any other curve is approximately inversely as its degree. The radius of a 10 degree curve is one tenth that of a one degree curve. This relation is not exact. A one degree curve is a very light curve, a ten degree curve about the sharpest in general use on Eastern trunk lines, a 24 degree curve about the sharpest on Western mountain lines, and 40 degree curves about the sharpest in railroad yards. Curves of 90 feet radius occur on the elevated railways of New York.

The Gauge of a railway is the cross distance between the inner sides of the heads of the rails. Standard gauge, almost universally used in the United States, is 4 feet 8½ inches. A gauge of one metre is used to some extent in the Spanish-American states, in Japan, Russia, and some other European countries. Until within a few years a gauge of 7 feet was in use in England. A gauge of 4 feet 9 inches is in limited use in the United States. A gauge of 3 feet was used to some extent in the United States, but has been almost entirely replaced with standard gauge. The transfer of the cars of one road to the tracks of another, making frequent unloading and reloading unnecessary, requires the tracks of any one continent, or country, to be of practically one gauge.

Traction is the act of drawing. That which enables a locomotive to draw a train is the friction between the driving wheels and the rails. When the pressure of the steam in the cylinders, transmitted through the connecting rod, tends to turn the driving wheels as the fly wheel of a stationary engine is turned, the friction between the wheels and the rails prevents such turning, and causes the wheels to roll along the rails carrying the locomotive and train with them. The amount of this friction varies with the condition of the rail. In summer, with a clean rail, it averages about one fourth of the insistent weight; in winter it is about one fifth; and when sand is used in summer, it may be increased to about one third of the insistent weight. Thus, if a locomotive weighs 209,000 pounds, 144,600 pounds of which is carried on the driving wheels (proportions of an existing modern heavy passenger locomotive), the average maximum pulling force that can be exerted by the locomotive in summer will be about one fourth of 144,600 pounds, or 36,150 pounds. This quantity is known as the tractive effort of adhesion. The locomotive will be able to exert this pull if the boiler and cylinder capacity is sufficient. It usually is when the speed is very low, but since a boiler is designed to give a certain maximum horsepower, when the speed is fast, the pull must be correspondingly light. Practical considerations make it impossible to design a boiler that will permit the development of the full tractive effort of adhesion at high speed. A locomotive of horsepower P , driven at a speed of S miles an hour will be able to exert a pull in pounds equal to $375 P \div S$.

This is a theoretical value and must be discounted about 10 per cent because of frictional losses in the engine. With slow freight trains speeds of from 5 miles to 10 miles an hour may be permitted, and hence the full tractive effort of adhesion may be had on the steep grades where it is required, and greater speed may be made on the more level stretches where the tractive effort required is not so great. The most economical speed for freight trains is a disputed question. It is generally considered to be the fastest speed the train can make over the whole road or division when the locomotive is loaded with the greatest load it can draw at minimum speed on the steepest, or ruling, grades.

Train Resistance is measured by the effort required to draw a train on a straight and level track. This effort depends on the condition of the track and wheels, atmospheric temperature, the lubrication of the bearings, the direction and force of the wind, and the speed of the train. Many efforts have been made to devise a formula that shall correctly express the effort for varying speeds, but as may be inferred from the number of variable conditions, no formula giving precise values is possible. Freight train resistance is usually considered to be about 5 pounds for each ton of weight of train for usual freight train speeds of from 12 miles to 15 miles per hour. This means that if a train weighs 1,000 tons, a tractive effort of 5,000 pounds will be required to draw it on a straight and level track at usual freight train speed. To start the train will require a greater effort, because the resistance at starting is much greater than at sensible speeds. Were it not that by reason of the springs in the draught rigging the train is started a car at a time, no locomotive could start the train it habitually hauls over the track. This does not apply to fast passenger trains, the locomotives of which, being never so heavily loaded, have a surplus of tractive effort for starting quickly. Freight train resistance is least at a speed of about 6 or 8 miles an hour, and increases nearly as the speed, being about 8 or 9 pounds at 25 miles an hour. Train resistance is sometimes known as rolling resistance. There are two other sources of resistance taxing the adhesion, or tractive effort, of the locomotive, namely, grade resistance and curve resistance.

Grade Resistance is the action of gravity on a train on a grade tending to pull the train down the grade. It amounts to practically 20 pounds per ton of train weight for each per cent of grade rate. Thus, a grade rising 1 foot in 100 is a one per cent grade, and offers a resistance to an ascending train of 20 pounds for each ton of train. A grade rising 3 inches in 100 feet is a 0.25 per cent grade, and offers a resistance of 5 pounds per ton of train, or doubles the traction necessary on a straight and level track. Such a grade is considered a light grade, a 0.5 per cent grade is a moderate grade, and a 1.0 per cent grade a heavy grade, though on mountain roads in the Western United States grades of 4 per cent are common, and there are some heavier. When grades exceed 5 per cent or 6 per cent they are usually operated by cable or by specially designed locomotives carrying a gear wheel which engages in a rack built along the track. Perhaps the most elaborate cable line is the Mahanoy plane of the Philadelphia and

Reading Railway, used to lift coal out of the Mahanoy Valley. Examples of rack railways are the Mount Washington Railway and the railway up Pike's Peak, planned for tourist and pleasure travel.

The Ruling Grade of a road, or division, is that grade which, because of its resistance, limits the train the locomotives used can haul. Such a grade therefore determines the number of trains necessary to do a given volume of business and is the most important feature of railway design. The ruling grade is not necessarily the steepest grade on the road. The steepest grade may occur but once, and be operated by assistant engines, a single locomotive hauling the train, heavier than it could haul unaided over the steepest grade, over the remainder of the line. Or the steepest grade may be so short that the train approaching it at high speed is carried over by the combined effort of the locomotive and the energy stored in the train by reason of its high speed. Such a grade is known as a momentum, or velocity, grade. To determine the load a given locomotive can haul on a given grade, Divide the tractive effort of the locomotive by the sum of the rolling and grade resistances, the result will be the gross load in tons. To determine the load behind the tender, Subtract from the foregoing result the weight of engine and tender. The locomotive mentioned earlier in this article, having a tractive effort of adhesion of 36,150 pounds, on a 0.25 per cent grade at low speed, could just draw a load determined by dividing 36,150 by 5 pounds per ton rolling resistance plus 5 pounds per ton grade resistance, or 10 pounds, giving 3,615 tons gross load. The total weight of such a locomotive and its loaded tender would be about 172 tons, therefore the net load behind the tender would be 3,443 tons. It is frequently claimed that an electric motor car can climb a steeper grade than can a steam locomotive, the popular belief being that some attraction between wheels and rails in the case of the electric car is the cause. It is true that an electric motor car of usual form can ascend a steeper grade than can a steam locomotive of usual form and equal weight and power. There are two reasons for this: 1. Gearing is a more certain and steadier method of transmitting power at low velocities than the reciprocating motion of steam pistons and connecting rods. 2. As usually built there is a motor on each axle of a motor car making all the wheels driving wheels, and the total weight available for traction, while a considerable proportion of the locomotive is carried on truck wheels, and hence is not only unavailable for traction, but is a direct tax on the tractive effort that is available. Assuming the high value of 10 pounds rolling resistance, an electric motor car with a motor on each axle would be just about in equilibrium, if it could start, on a 24½ per cent grade, while the locomotive mentioned earlier in this article would be in equilibrium on a 16⅓ per cent grade. No such grades could be operated. About the steepest grade operated by an electric car is 13 per cent, but such a grade is dangerous, and safety appliances should be used. The danger lies in the fact that if the wheels once begin to slip, the coefficient of friction is immediately reduced to less than one tenth, and moreover, the brakes are not infallible. Driving wheels of locomotives are seen to slip

even on straight and level track, particularly at starting. This is because the great resistance to starting overcomes the adhesion, or because the engineman admits steam to the cylinders too suddenly and freely.

Assistant Engine Grades steeper than the ruling grade may be occasionally necessary to avoid great expense of construction. When such grades occur at or near a station, or yard, a switching engine may be used to help the trains up the grade, but when such grades occur out on the line, special engines must be kept at the foot of the hill. Such engines help the heavy trains over the hill and return light, without train, to the foot. To determine how steep a grade may be operated with the aid of one assistant engine of the same power as the through engine, Add the weight of the assistant engine to the weight of the through train, and find on what grade the combined tractive effort of the two engines just equals the total resistance of the entire train. The problem is just the reverse of finding the load an engine can haul on a given grade.

Momentum Grades find favor with railway managers of the Western United States and Canada, and are in operation in those portions of America, enabling heavier, and consequently fewer, trains to be run than would otherwise be necessary. Managers of heavy traffic lines in the Eastern United States regard the consideration of such grades with disfavor, holding that the accidents of traction are so great and uncertain that it is unwise to send out a locomotive with a train of greater weight than that with which the locomotive can start from rest on the steepest grade over which it must pass. The consideration of momentum grades involves two problems, one when a new line is being built, the other when re-arranging the train loads for locomotives on an existing line. The first is the determination of the length of grade, steeper than the ruling grade, that can be surmounted by a given locomotive loaded with a train proportioned for the ruling grade; the second is the determination of the weight of the train that a given locomotive, aided by velocity of approach, can carry over a grade of given rate and length. In each case the velocity with which the grade may be approached must be known. Neither of these problems is capable of exact solution, but both are capable of comparatively simple approximate solution. On an existing line a dynamometer car is of great service in studying economical locomotive loading and grade arrangement.

High Mountain Levels, if narrow ridges, may be tunneled; but if broad table-lands with steep approaches, may be reached by one of several methods adopted to secure practicable grades: (1) Zig-zag development, which means laying the line back and forth across the general direction of the route, gradually climbing the hill on a permissible grade, turning nearly a half circle at each end of a lateral stretch until the summit is reached. (2) Switch-back development, which is zig-zag development without the necessary room for turning at the ends of the lateral stretches necessitating the use of switches at these ends and the backing of the train up alternate stretches. Switch-backs must always be located in pairs to permit regaining a for-

ward movement of trains. (3) Spirals or loops, which are formed by the line advancing in a more or less continuously curving path, constantly rising and finally crossing itself over a tunnel or bridge. Noted spirals in the United States are the Union Pacific Georgetown branch loop in Colorado, and the Southern Pacific Tehachapi loop in California. The Mount St. Gothard railway has one spiral on the Swiss side and four on the Italian side of the mountain, almost complete circles, and almost entirely in tunnel.

Curve Resistance arises from two principal causes: (1) Car wheels are fastened rigidly to the axles and hence do not turn independently. They are of practically the same diameter, and in rolling a given distance should make the same number of revolutions. But the outer rail of a curve is longer than the inner rail, and hence either the outer wheel must slip forward on the rail, the inner rail must slip backward, or both slippages must occur. (2) The direction of motion of the wheels must be constantly changing. This change is affected by the pressure of the flange of the forward outer wheel of a car truck against the side of the rail head. Both of these conditions introduce friction which must be overcome. The amount of curve resistance is not definitely known, but such observation as has been made indicates that it varies from a half pound per ton of train weight per degree of curve to two pounds per the same units. It is usually assumed at one pound. Thus, to draw a train on a 5 degree curve will require an effort of 5 pounds per ton of train weight, or as much as to draw a freight train on a straight and level track. If such a curve occur on a 0.25 per cent grade, the total effort required to draw the train will be 15 pounds per ton, 5 pounds for rolling resistance, 5 pounds for grade resistance, and 5 pounds for curve resistance. When curves occur on grades approximating the ruling grade so that the combined resistance of curve and grade exceeds that of the ruling grade alone, the grade throughout the curve is reduced sufficiently to make the total resistance no greater than that offered by the ruling grade. This is called compensating for curvature. The amount of reduction is usually 0.05 per cent for each degree of curve.

Elevation of the Outer Rail.—The passage of a train at sensible speed around a curve generates centrifugal force tending to cause the train to leave the rails or overturn. This force is greater in proportion to the square of the speed, and less as the radius of the curve is greater. It is counteracted by canting the track, usually called elevating the outer rail, so that the effect of gravity tending to pull the train down the inclined plane toward the centre of the curve shall just equal the centrifugal force generated, or rather, so that the resultant of the weight and centrifugal force shall be perpendicular to the plane of the track. It will be evident that in passing from a straight line to a curve, since the centrifugal force is instantly generated, the full theoretic cant of the track should begin at the beginning of the curve. This is possible with the modern easement curves, but was impossible with curves as formerly laid out when the circular curve was itself tangent to the straight line. The practice then was to begin the canting back some distance on the

straight line, increasing it gradually till the full amount required was had at the beginning of the curve.

Cost of Operation is an important item of information to the locating engineer. He is particularly interested in the cost of running trains, usually stated by the train mile, that is, one train run one mile. From this cost known in great detail, he separates those items that vary with the physical characteristics of the road and which may therefore be influenced by his design, and endeavors to determine what additional cost would result from the addition of a mile or a foot to the length of the line, the cost resulting from the introduction of a degree of curvature, or a foot of rise and fall in the grade line, and the cost resulting from an increase in the ruling grade. Excluding fixed charges, but including all general expenses of operation, many of which are independent of the number of trains run, and even considerable variations in the physical characteristics of the track or motive power, or amount of traffic, the average cost of running one train mile in the United States is about \$1.18, having increased about \$0.22 since 1898, before which year the cost was practically constant, varying only a few cents for a number of years. Heavy freight trains cost from \$1.20 to \$1.80 or more per train mile, averaging about \$1.40, while passenger trains cost from \$0.75 or less, to as much as heavy freight trains, averaging about \$1.10 per train mile. The cause of the increase in cost is partly due to an increase in the weight of trains of both classes, and the increased elegance and speed of fast passenger trains. Operating expense is divided into four general items, each made up of a multitude of minor items for which reference may be had to the Reports of the Interstate Commerce Commission. The four general items with their several contributions to the train mile cost are:

| | |
|----------------------------------|--------|
| Maintenance of way and works.... | \$0.26 |
| Maintenance of equipment..... | 0.225 |
| Conducting transportation..... | 0.65 |
| General expenses..... | 0.045 |
| Total | \$1.18 |

From the detail items above referred to the cost of operating a train unit of distance, curvature, and rise and fall, may be approximated. Based on a train mile cost of \$1.00, these costs will be as an average for the United States about as follows: A train degree of curvature, \$0.0006; a train foot of rise and fall, from nothing to \$0.005, depending on the rate of the grade on which the rise occurs; a train foot of distance, \$0.0004; a train mile of distance from \$0.35 to \$0.90, according to the distance. If it is estimated or known that the train mile cost on any particular road is \$1.40 then the foregoing values should be multiplied by 1.4. Only heavy passenger and maximum freight trains should be considered in comparing different ruling grades, but all trains are affected by curvature, rise and fall, and distance.

Railway Revenue is a matter of importance to the railway engineer, for he must not plan a line of light traffic on so expensive a scale as one of heavy traffic. He can not spend so much to secure low grades for a line that

will probably run one or two or five trains a day as for one that will probably run 10 to 50 trains daily. For the purpose of design, the probable business is best estimated by the number of daily trains, but for the purpose of reporting on the desirability of a proposed new line, the estimate must indicate the probable revenue in money. In either case the only method of making a rational estimate is to compare the producing character of the territory to be traversed, with that of some similar territory already served by a railway, and to note the revenue of that railway. To compare population is not enough; the nature of the industries to be served, or that are likely to soon follow the construction of the road, must be considered.

Railway Location consists in selecting the general route between two adopted termini, and the detail work of so fitting the line to the ground along the adopted route by judicious curvature and grades that the cost of construction shall be an economic minimum. This may be the ultimate practicable minimum, but will not ordinarily be so. The effort of the locating engineer is to so design the alignment and grades that the net difference between revenue and the sum of operating expense and interest on first cost shall be a maximum. This work requires the greatest skill and judgment of any branch of railway design. The field work of fitting the line to the ground involves ordinary surveying methods. The surveys, after a reconnaissance which determines the general route, are two, the preliminary survey and the location survey. Practice has varied as to the methods of doing the detail work, but in general the preliminary survey is a topographical survey of a belt from 200 feet to 1,000 feet wide, within which the located line will lie, furnishing a map on which a centre line is planned to fit the ground as represented on the map, and the location survey consists in placing the line, thus designed, on the ground. Two maps are always made on a location survey, one showing the horizontal alignment known as the map, another showing the vertical alignment, the grades, known as the profile. The profile shows both the undulations of the natural ground surface and the undulations of the surface along the centre line as it will be when the road is graded. Generally an effort is made to so draw the grade line on the profile that there shall be as much of the natural surface above it as is below it, thus making the portion to be cut away equal the portion to be built up by embankment. This is generally economy, but as cuts are troublesome to drain, and to keep clear from snow in northern latitudes, a road is laid out in embankment so far as is economically possible. The most important item in railway construction, after providing the necessary strength to carry the trains, is drainage. When a cut or excavation lies across the general direction of the prevailing winter winds, it is likely to collect drifts. These are sometimes prevented by building open board fences parallel with, and some distance from, the cut, causing the drift to form outside the cut. In mountainous districts subject to heavy snow drifts, the track is sometimes protected by wooden sheds entirely covering it. Many miles of such sheds occur on the Central Pacific division of

the Southern Pacific Railroad through the Sierra Nevada Mountains, and on the Canadian Pacific Railroad. These snowsheds are very costly to maintain, requiring constant watchfulness to prevent fire, and the maintenance of fire fighting apparatus ready at all times. In determining the economic grades and curvature to be used, the locating engineer applies his knowledge of the facts and principles mentioned in the preceding paragraphs of this article. He determines how much he may spend to avoid a degree of curvature, how much to avoid a foot rise in the grade line, how much to shorten the line a foot or a mile, and how much to reduce the ruling grade below that which seems to give the lowest first cost; he determines where pusher grades may be introduced to advantage, and where velocity may be counted on to assist in surmounting some steep short grade that low first cost suggests. After the location is completed, and sometimes while it is yet in progress, the work of construction begins. Before this, details of rail section, cross ties, roadbed, etc., must be determined.

Railway Right of Way is the name given to the strip of land secured by the railway company for its use in building and maintaining its road. In the United States this strip is usually 100 feet wide, with additional ground for stations, shops and yards, and extra width along the line where the construction work is so heavy as to require it. Where an embankment is so high, or an excavation so deep that the base width of the one or the top width of the other is more than 100 feet, a retaining wall must be built or additional width of right of way secured. In cities it is generally advisable to build the walls, but in the country economy will be secured by buying extra right of way.

Railway Roadbed, the top of which is known as sub-grade, is from 14 feet to 18 feet wide where the road is in embankment, and from 20 feet to 26 feet wide where in excavation, for single track roads. The extra width in excavations is to provide room for drainage ditches on each side of the track. The side slopes of the embankments are usually one and one half horizontal to one vertical, which is about the angle at which ordinary earth will stand. Rock slopes may be made vertical in excavation and at 45 degrees, one to one, in embankment. Earth slopes are sometimes taken out in excavation at one to one, but they do not long stand at this slope, and the slight economy obtained in first cost is at the expense of additional cost of maintenance in keeping the ditches open.

Railway Ballast is the material in which the cross-ties are imbedded, and which serves the purpose of distributing the load on the ties over the roadbed, holding the track in place, and providing drainage for the track. The requirements for good ballast are that it shall be durable, shall yield no dust, shall be firm and porous. Fine broken stone or gravel make excellent ballast. Other materials used are furnace slag, cinders, burnt clay, and ordinary earth. In value these are about in the order given. For light traffic roads there should be not less than six inches of ballast under the ties, and for the heaviest traffic there need not be more than 16 inches. If the ballast is quite porous, as broken stone, it is carried up to the top of the tie

throughout its length and a little beyond the ends, and then sloped off to the roadbed, but if it is less porous, as compact sandy or loamy gravel, it is carried up to the top of the tie, or 3 or 4 inches above it, in the middle, from where it is sloped down to the bottom of the tie at its ends, and then to the roadbed.

Railway Cross-ties are usually of wood. A few steel ties are in use, and concrete steel ties are in experimental use. A hard wood, not quickly rotted by exposure, is desirable for a wooden tie. Oak and Southern pine are much used. Chestnut, cedar, redwood, bois d'arc, Douglas fir, and other woods, are used in localities where they are readily obtainable. Untreated with preservative, railway ties of good quality will last from seven to eight years, and in the alkali soils of the Western table-lands much longer. Comparatively poor soft wood ties, preserved by Burnettizing, the Wellhouse process, or creosoting, will last from 12 to 15 years or longer, and are much more economical than hard wood ties untreated. Probably not far from 100,000,000 cross-ties are used in the United States annually. The common size is six inches deep, eight inches wide, and eight feet long. Some are larger, and a few smaller.

Railway Rail designing was formerly a matter occupying considerable attention, and many forms were devised and used. The best form is still undetermined and under consideration by eminent railway engineers, but, with a few notable exceptions, American roads use exclusively what is known as the American Society of Civil Engineers' section, and modern designing consists simply in determining the weight to be used, and the chemical composition and physical treatment of the metal. Rails are known by the weight per lineal yard of one rail. A 60 pound rail weighs 60 pounds per lineal yard and has about 6 square inches in its cross section. The rail is divided into head, web and flange; and in the Am. Soc. C. E. section, 42 per cent of the section is in the head, 21 per cent in the web, and 37 per cent in the flange whatever the weight. The principal features of this section are the proportions of the metal in the three parts, the equality of total height and base width, the vertical sides of the head, some engineers advocating heads widening downward, and the small radius curves for the upper corners of the head. The section has proven well adapted to rails of less than 80 pounds per yard, but not so well adapted to heavier sections, the reason generally assigned being that the disproportion of thickness of head and flange makes impossible continued rolling at low temperature, which is said to harden the head and make it more durable. A section designed by P. H. Dudley for the New York Central Railroad overcomes this difficulty to some extent. Other types of rail are the Sayre, designed by R. H. Sayre for the Lehigh Valley Railroad, and the Sandberg type used somewhat in Europe. The standard type of rail in Great Britain is known as a bull head rail. It has two heads instead of head and flange, and is carried in cast iron chairs in which it is fastened by wedges. It was originally designed to be reversible, but it was found that by the time the head in use was worn the head in the chair had become so

battered that it could not be used. The head in the chair is now rolled only large enough to provide the necessary bearing and wedging space. Rails are generally 30 feet long, a few of each lot being one or two feet shorter. There is a tendency to increase the length of the rail in order to lessen the number of joints, and a good many 33 feet rails are in service, some 45 feet, and a few 60 feet. Heavy street railway rails are almost always rolled 60 feet long.

Rail Jointing is as yet an unsolved problem. The object to be attained is to make the track at the joint as strong, as rigid, and as flexible as other parts of the track, in short, to make the jointed track act as a continuous track. There are two types of joints, known as supported and suspended joints. In the first the abutting ends of adjacent rails are on a tie, in the second between two ties. What is known as a bridge joint is a suspended joint in which a bar or plate of metal resting on the ties adjacent to the joint supports the rail ends. Common forms of splice bars, or joints, are the ordinary angle bar splice, the continuous rail joint, the Weber joint, and two modifications of the angle bar splice, known as the Bonzano, and the 100 per cent joint. Rails are fastened to the ties by hook headed spikes. Sometimes plates known as tie plates are used between the rail and the tie, to save wear on the tie and to form a lateral brace for the rail. Rail braces are used on curves, to brace the outer rail against the pressure of the wheels, and at switches.

Switches are devices by which a train is enabled to leave one track or enter another. They consist essentially of two movable rails called switch rails, which may be set to guide the wheels to the main track or to the turnout, and a frog, which permits the flange of the wheels to cross the rail of the main track where it is crossed by the outer rail of the turnout curve. There are various kinds of safety switches and frogs, devised in general to provide an unbroken main track.

Side Tracks for passing trains must be built along single track roads at intervals depending on the traffic. They may be long enough to hold from one to four trains. The maximum length of a train is not the same on all roads nor on all divisions of one road because of differences in ruling grade and locomotive power. Lengths of side tracks will differ accordingly. It is hardly practicable on single track roads to handle trains of more than 65 to 70 cars. Such trains will require about a half mile of siding per train. Double track roads require sidings to permit fast trains to pass slow trains. Even four track roads require occasional passing sidings, and all roads require sidings at stations for handling freight.

Railway Yard is the term applied to the space occupied by a railway at a station. At principal stations, yard design, meaning the planning of the arrangement of the side tracks in the yard, is a matter of great importance, requiring experience and judgment. A design is usually the result of the combined efforts of the Chief Engineer, the Master Mechanic and the General Superintendent. Beside the necessary shop and roundhouse tracks, and tracks for the storage of cars needing repairs, or temporarily out of service, each yard will have two distinct sets of

tracks, one for freight in each direction. Each set will have its incoming storage tracks, its classification tracks, on which the mixed freight of an incoming train is sorted according to its class, whether live stock, perishable goods, or other freight, and whether through or local, and its outgoing storage tracks on which the trains are made up anew for forwarding. Yards should be designed to make the movement of freight through them continuous. There are three methods of handling the cars, known as "push and pull," "poling" and "gravity." By the first a shifting or switch engine is coupled on the rear of a newly arrived train, pushes it ahead while a trainman uncouples the first lot of cars, called a cut, for some classification track, stops as suddenly as possible, when sufficient speed has been attained to send the cut to its proper place, pulls the remainder of the train back for a new start, and again pushes it forward, sending a second cut ahead, and so on till the whole train is distributed. The severe treatment of the cars, and the considerable total distance traveled by the engine will be apparent. By the second method, the switching engine runs on a track alongside the train to be distributed, the first cut is uncoupled, a pole is placed against the rear of the rear car of the cut and the forward end of the engine, which then pushes the cut ahead till it has attained sufficient velocity to send it to its proper place, and then returns for a second cut and so on. The lessened wear on the cars will be evident. By the third method a hump or hill is made in the track up which the engine pushes the train till the first cut is ready to run down the other side, which it is permitted to do, the incline giving it sufficient speed to carry it to its proper classification track. The first cut is followed by the second and so on. The cars are not severely used, and the engine travels simply the length of the train. Such a gravity yard furnishes the most economical method of distributing cars. If the road is a double track road, the main tracks should lie wholly without the yard, one track on each side, to avoid the necessity of any crossing of main tracks at any time. A single track road should lie on one side of the yard, the two sections of which may lap. A car once received from a main track should not touch it again till made up in a train to go forward. Comparatively few yards are well designed, having grown from small beginnings, but many new ones are being well laid out, and some old ones remodeled to conform to the requirements of increased business. Tracks in yards and sidings constitute more than one fifth of the total trackage of the United States.

Water Supply stations on busy lines occur about once in five miles and are rarely farther than 10 miles apart. In cities water is usually taken from the public supplies through suitable stand pipes or track cranes. Between cities it may be obtained from large wells, from near by streams, lakes or ponds, or from specially constructed reservoirs. An elevated wooden tank holding about 50,000 gallons or less is usually constructed at each water station. The height is sufficient to permit running water rapidly to the engine tender tank. A few roads running heavy fast passenger trains maintain track tanks, which are steel troughs about a quarter of a mile long in the centre of the track. These

RAILWAY FREIGHT CAR MILEAGE

troughs are kept full of water by a near by pumping station, which also supplies steam and circulation to prevent freezing in winter. Water is taken by the locomotive without stopping. A scoop under the tender is lowered into the water at the beginning of the trough, and the water is forced up into the tender tank by the rapid forward movement of the locomotive. These tanks are expensive luxuries, necessary only to long distance high speed travel. In the arid districts of the West, water supply is a serious problem, solved often by the use of water trains conveying water from the nearest source to points where it must be on hand, but is not to be found. Water must be of good quality for steam making, and not infrequently is brought several miles in pipes because local water at a station is unfit for use in boilers. Various water purifying and softening processes are also in use. Water is supplied to the tanks by gravity from high storage reservoirs, or by pumps actuated by wind mills, steam, gas, or oil, engines. The cost of water supply amounts to about $\frac{5}{8}$ of one per cent of the total cost of railway operation, or about $\frac{3}{4}$ per cent train mile.

Prof. of Civil Engineering and Director School Applied Sciences, Iowa State University.

Railway Freight Car Mileage in the United States. The number of miles run daily, on the average, by freight cars is an indication of their usefulness and money-earning capacity. As the freight earnings constitute 69.4 per cent. of the total earnings of railroads in the United States, it is most important to keep the cars moving, so that their mileage and their earnings will be as large as possible.

Freight car mileage is classified as loaded and empty. Usually two-thirds of the total mileage is made when the car is under load, and one-third when it is empty. Of course, only the loaded mileage produces earnings, the empty mileage being made in moving the car from point to point in seeking the load; naturally a constant effort is directed towards reducing this empty, nonproductive mileage.

Poor's Manual of the Railroads for 1905 gives the following figures:

| | |
|---|---------------------------|
| Miles of railroad operated.... | 213,828 miles |
| Tons of freight moved..... | 1,277,771,573 tons |
| Tons of freight moved one mile | 173,628,034,040 ton miles |
| Freight cars..... | 1,728,903 cars |
| Total mileage of freight cars..... | 14,353,650,056 car miles |
| Freight earnings..... | \$1,374,102,275 |
| Total earnings..... | \$1,977,638,713 |
| Average distance each ton is hauled | 136 miles |
| Average number of ton miles per freight train mile..... | 320 ton miles |

From these figures it is found that on an average each freight car earned \$705 yearly; that it moved 8302 miles, or made that many car miles; that on the average it moved daily 22.7

miles; that during the year it carried 739 tons of freight, or 100,426 tons of freight one mile; and that there are 8.1 freight cars for each mile of railroad.

The average mileage made by freight cars is increased by long haul freight; by the prompt movement of freight after it is loaded; by a large percentage of high grade perishable stock or refrigerator car freight, which, necessarily, has to move promptly; by proper freight tracks and yards, so that the freight traffic is not delayed by the passenger traffic, or by lack of handling facilities; by the strict collection of charges for car service, so that cars are loaded and unloaded promptly; by not overloading freight trains; by a high daily rental paid for the use of cars in preference to a mileage payment; by keeping the cars and power in good repair; and by many other phases of good operation.

The mileage is influenced unfavorably by a short average freight haul; by a large percentage of low grade or slow moving freight, such as coal, which is often allowed an extra time for unloading before a charge is made for the use of the car; by poor track and yard facilities; by failure to charge and collect car service, thus allowing cars to stand under load an unduly long time; by overloading freight trains, causing delay on the road; by slow movement of freight after it is loaded; by a low mileage or day rate for payment for the use of cars; by equipment in poor condition; and many other phases of poor operation.

Naturally refrigerator cars loaded with perishable freight, which move long distances and must necessarily move promptly, make the greatest mileage, while coal, flat and gondola cars loaded with slow moving freight make the poorest.

The average mileage made with freight cars on the different roads varies from as low as ten miles to as high as 35 or 40 miles daily. The figure of 22.7 miles per car per day, which is the average made by all of the roads of the United States, appears to be very low; but then it must be remembered that the average haul is only 136 miles. Applying the daily rate of 22.7 miles to 136, we find that it gives an average of six days as the period between loading, or the time required for the round trip. When it is remembered that included in this figure of six days is the time required to load and unload the car, move it to obtain a new loading, and repair it when repairs are needed, the figure does not appear so bad. Car Service Associations usually allow two days free time for either loading or unloading a car, before a penalty is charged for the use of the car, and if one day beyond the four thus taken up be needed to place the car for its next load, it only leaves one day in which the car must be moved, and repaired when it needs repairs.

This illustration is given to bring out strongly the point that during the greater part of the time freight cars are occupied in the loading or unloading, or by waiting for a load; that only during a small part of the time is a car actually being moved. It shows the great necessity for quickening the time required for loading and unloading, and, of course, indirectly shows the necessity for car service associations to make and collect a charge for the use of cars

RAILWAY HEAVY FREIGHT TRAINS

when too much time is taken in either loading or unloading them. That is, the way to make the greatest gain in freight car mileage is by reducing the time a car is not moving.

The average length of freight haul per ton, as has been mentioned before, greatly affects the mileage made by the cars. Poor's Manual for 1905 gives the following figures as to the average freight haul per ton, which show much variation for different parts of the country:

| | MILES. |
|---|--------|
| New England States..... | 86 |
| Middle States..... | 109 |
| Central Northern States..... | 141 |
| Gulf and Mississippi Valley States..... | 143 |
| Southeastern States..... | 192 |
| Northwestern States..... | 209 |
| Pacific States..... | 213 |

Naturally, the New England roads cannot make as good average mileage with their cars as the roads in the Pacific States.

The following are some of the important points watched by many railroads in order to increase the mileage made by freight cars:

Monthly statements are made showing the mileage made by freight cars of the various kinds on each Superintendent's division. These statements give comparison with preceding periods, and with the performance on each other division of the system. Thus, the statement at once shows the part of the system where the poorest performance of the cars is being made, and attention is naturally directed to bettering the conditions at this point.

An effort is made to put as much business as possible in the through trains that will run long distances without switching in intermediate yards. Thus, the cars move continuously for long periods.

At all points where business originates, it is necessary to hold empty cars in order to provide for the business. A number of men are constantly employed in watching them, to see that no more than necessary are kept on hand.

At terminals the number of cars to be unloaded is carefully watched, so that, in case they accumulate faster than they can be unloaded, arrangements are made by embargo, or by reduction of the supply of empty cars at the loading point, to avoid an accumulation of loads at the unloading terminal.

An increase of ten per cent. in the mileage made by freight cars is equivalent to building that much more equipment. The building of new equipment is frequently made unnecessary by increasing the mileage of existing equipment.

C. S. SIMS,

Assistant to the President, Erie Railroad Company.

Railway Heavy Freight Trains. The weight of freight trains in the United States has increased enormously within the last 10 years as may be seen by the following table, which shows the increases on a few of the most important roads in various sections of the country:

| RAILROADS. | 1895 | 1896 | 1897 | 1898 | 1899 | 1900 | 1901 | 1902 | 1903 | 1904 |
|--------------------------------------|------|------|------|------|------|------|------|------|------|------|
| Lehigh Valley | | | | 412 | 424 | 448 | 467 | 464 | 486 | 486 |
| New York Central | | | 290 | 320 | 361 | 368 | 302 | 387 | 421 | 419 |
| Pennsylvania | | | | | 470 | 478 | 481 | 518 | 527 | 501 |
| Louisville & Nashville | | | 179 | 194 | 216 | 236 | 222 | 231 | 211 | 214 |
| Norfolk & Western | | | 325 | 355 | 384 | 435 | 452 | 476 | 486 | 488 |
| Chesapeake & Ohio | | 325 | 352 | 379 | 450 | 501 | 533 | 538 | 538 | 538 |
| Southern | | 162 | 173 | 176 | 188 | 203 | 222 | 226 | 218 | 225 |
| Illinois Central | | | 104 | 191 | 209 | 222 | 275 | 325 | 335 | 332 |
| Chicago & Northwestern | | | 141 | 152 | 161 | 216 | 232 | 250 | 232 | 225 |
| Chicago, Milwaukee & St. Paul | 152 | 167 | 167 | 175 | 187 | 205 | 203 | 285 | 281 | 280 |
| Lake Shore & Michigan Southern | 318 | 322 | 321 | 352 | 427 | 455 | 531 | 577 | 615 | 588 |
| Southern Pacific | | | | 220 | 226 | 240 | 244 | 261 | 267 | 275 |
| Northern Pacific | | | 210 | 313 | 336 | 391 | 381 | 401 | 384 | 401 |
| Great Northern | | 256 | 281 | 316 | 336 | 357 | 381 | 418 | 447 | 447 |

In the Car Record Office at intervals of every five days the records of movement and location of cars are gone over, and the Superintendent of Car Service writes to the Agent, or Yardmaster at whose station or yard a car has been located for an unduly long time, inquiring as to the cause and suggesting the movement of the car.

Once during each month a statement is made, showing all cars which have not moved for a period of five days or more on each Superintendent's division. This statement is made so that it compares with the preceding period, and with each division. It is a constant reminder of the necessity of moving the cars,—an effort naturally being made to have each succeeding statement show fewer old cars.

Card waybills under which a car is moved are often stamped with the date of arrival of the car at any point. Thus, by looking over the card waybills is ascertained the length of time any car has been at any point, and the old cars can readily be checked.

This table gives the average weight of train in tons of 2,000 pounds hauled by the roads during this period. In some cases this is revenue tonnage, and in others total tonnage, but as the same unit is used for the figures of any one road, the proportionate increase can be easily discerned. As a rule roads lying east of the Mississippi river have not increased the weight of train is as great a proportion as the other sections, but in 1899 the trains of these eastern roads were generally heavier than those of the west, so that there was less opportunity for increase. It is also of interest to note that there has been comparatively little increase from 1902 to 1904, but there have been some very great increases within the 10-year period as, for instance, will be seen by referring to the Lake Shore record, which averaged 318 tons in 1895, and 615 tons in 1903, or nearly double, and C., M. & St. P. has accomplished nearly the same proportion of increase, but even now its train load is not as great as the Lake Shore's was 10 years ago. This is accounted for by the

RAILWAY HEAVY FREIGHT TRAINS

fact that the latter road is nearly straight, with light grades, while the former has hills that are possibly three times as steep.

We must not confuse, however, the train loads given in the table with what is actually hauled by the locomotives, as the Lake Shore road has engines which can haul 3,000 tons or more back of the tender. The figures are the average train loads for main line and branches, and, moreover, do not include the weight of the cars themselves, which may run from one half to one and one half times the load, depending upon whether it is heavy or bulky. One of the transcontinental lines recently grouped its locomotives so that trains of from 1,350 to 2,600 tons could be hauled westbound, that is, the load back of the tender lay between those limits for different portions of the line, the engines being distributed according to the grades, so that a constant train load could be taken as far as possible. The first 450 miles were of undulating profile, having .8 per cent. grades and 1,500 tons were pulled over this portion. Beyond this the grades were lighter, and with helpers at critical points the train load was 2,400 tons for a distance 600 miles. The following 500 miles had very heavy mountain grades, and even with three large engines the load was reduced to 1,500 tons. One hundred miles of descending grades permitted one en-

noticed that generally the cost has risen in this period, while it fell before; but we also see that the greatest increase in tonnage per train mile was made in the previous five years.

Examine, for instance, the Northern Pacific record, where the cost dropped from .70 to .47 between 1897 and 1900, and the train load increased from 239 to 391 tons, whereas, from 1900 to 1904 the load has only increased 12 tons (from 391 to 403), and the cost is about the same, viz., .46 cents. So, also, for the C. M. & St. P., the weight of train increased from 152 to 285 tons, and the cost dropped from 67 to 56 cents between 1895 to 1902, but since then the train load has decreased slightly and the cost has risen to .59. In this case also the lowest cost was accompanied by the heaviest train. The Illinois Central, C. & N. W., and Great Northern also show that the lowest cost corresponded to the years of heaviest train loads. Some of the other roads show a slight increase in cost in connection with a slight increase in weight of train, but this is due no doubt to heavier charges for labor and material.

In order to haul such trains much heavier locomotives are needed, and the following table gives the principal elements of the heaviest freight locomotives that were built during corresponding years as given in the engineering journals:

| ITEMS. | 1895 | 1896 | 1897 | 1898 | 1899 | 1900 | 1901 | 1902 | 1903 | 1904 |
|-------------------------------------|--------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| Total weight in tons..... | 87.5 | 92.5 | 86.0 | 115. | 110. | 125. | 105. | 132. | 142. | 167. |
| Adhesive weight in tons..... | 75.0 | 75.0 | 62.5 | 102. | 92.5 | 112. | 92.5 | 117. | 117. | 167. |
| Tractive force in pounds..... | 38,000 | 38,000 | 26,000 | 53,000 | 50,000 | 64,000 | 49,000 | 62,000 | 63,000 | 70,000 |
| Heating surface in square feet..... | 2,300 | 2,900 | 2,900 | 3,300 | 3,500 | 3,800 | 3,600 | 5,400 | 4,800 | 5,600 |
| Grate area..... | 35 | 35 | 34 | 35 | 49 | 42 | 52 | 59 | 58 | 72 |

gine to take 2,600 tons, but beyond this additional mountain ranges required the tonnage to be cut in half to tidewater 600 miles further. Thus the train would be broken nine times in covering 2,300 miles of road, but the profile and available locomotives did not permit of a closer adjustment. This gives some idea of the diversity of conditions with which large systems have to contend.

The partial effect attributable to increase in weight of train is shown in the following table which gives the average cost of hauling one ton, one mile in cents, during the same period. It must be remembered that there are many other items besides the weight of train which effect this cost, as variation in price of materials and labor. These latter have increased considerably within the last five years, and it will be

Of course, the introduction of large locomotives when purchased in considerable numbers, will have an immediate effect upon the average train load, but even if the total power of the road has a 10 per cent. increase in large engines, the general average would be but slightly raised. The C. & N. W. found that in 30 years the average tractive force of its locomotives on its lines had increased 150 per cent, which would mean a corresponding increase in train load, but we find that in ten years alone this road has nearly doubled its weight of trains. This indicates that the increased size of locomotives is not alone responsible for heavier trains, and while double heading has made some increase there is no doubt but that the system of tonnage rating is responsible for a large proportion of the increase. When locomotives are

loaded by actual weight of train instead of by number of cars, as was formerly the practice, the full power of the engine can be utilized and heavier average trains can be hauled.

There are limits, however, which should be observed in this practice, and while some dispatchers thought that if a heavy train was good practice a heavier one would be still better, and loads were added until the engine could hardly ascend the maximum grades, it has been frequently demonstrated that it is not only impossible to obtain a large monthly freight movement per engine by such overloading but it is also usually a very expensive practice; that is that if we wish to obtain the greatest ton mileage from a locomotive during a period of time, and also operate at the lowest possible cost, we must usually attach a considerably lighter train than the maximum which could possibly be taken over the heavy grades.

The tractive force of simple locomotives at slow speeds (8 to 10 miles an hour) is taken as eight-tenths of the product of the boiler pressure in pounds per square inch, the square of the cylinder diameter in inches and the stroke of the piston in inches, divided by the diameter of the driving wheel in inches. This tractive force is at the rail and the weight upon the drivers must be at least four times as great as the tractive force. A train can be hauled when the resistance (including engine and tender as cars) does not exceed the tractive force.

The resistance must be figured for speed, grade and curvature and also for inertia when starting or accelerating trains. The speed resistance below 20 miles an hour can not be expressed by any regular rule, and amounts to about as follows: 5 miles an hour, 5 lbs. per ton; 10 miles an hour, $5\frac{1}{2}$ lbs. per ton; 15 miles an hour, 6 lbs. per ton, and at 20 miles an hour, 7 lbs. per ton. Above this speed the resistance in pounds per ton is generally taken as one-fourth of the speed in miles per hour plus two pounds; at 20 miles an hour this also gives 7 lbs. per ton; and the weight of the engine and tender must be included as well as the weight of the cars.

For the resistance due to grades we must know the amount of ascent either in feet per mile or in per cent of length. The resistance per ton will be .38 times the number of feet rise per mile of track, or 20 times the per cent of rise when stated as a percentage, that is, 20 pounds per ton for a 1 per cent grade. Curvature has a resistance of about .7 pounds per ton per degree of curvature, but it is probable that locomotives with long rigid wheel-base about double these figures.

It requires a great deal of power to accelerate a train, that is to bring it to a given speed from rest, or from a lower speed to a higher speed. Including the rotative inertia of the wheels and axles it is necessary to exert a force in pounds per ton equivalent to 70 times the square of the speed in miles per hour divided by the distance in feet in which the acceleration is to be effected, or 95.6 times the speed in miles per hour divided by the time in seconds, if time instead of distance be considered in the calculations. If the speed is to be increased from a lower one to a higher one then in the first case we should substitute the difference between the squares of the speeds and in the

latter case the difference between the lower and higher speeds. In all cases the weight of the engine and tender must be included in making up the total resistance and this total must not exceed the tractive force as determined above.

The relative weight of cars and their loads also enters into the problem. It has been found by experiment that empty cars on a level track require a much greater force per ton to haul them than when heavily loaded, this being due no doubt to the fact that the wheel and axle friction has a smaller total weight into which to be divided. As a matter of fact it was necessary to allow about 30 per cent on a level for empty cars over a similar total tonnage of loaded cars. The resistance of a train can be considered as depending both upon the number of cars and the total weight and it has been suggested that this total resistance might be taken as 3.5 times the weight of the train in tons of 2,000 lbs. plus 50 times the number of cars in the train, the resistance so figured being in pounds at the tender drawbar, and on a straight level track with speeds not exceeding 10 miles an hour. From this rule we find that a car weighing $16\frac{2}{3}$ tons would have a resistance of 6.5 lbs. per ton, one of $33\frac{1}{3}$ tons a resistance of 5 lbs. per ton and one of 50 tons total weight a resistance of only 4.5 lbs. per ton.

Thus we see that the advent of 50 ton cars has the effect of reducing the train resistance not only by their lighter weight per unit of capacity but also by the fact that heavier loads are carried on an equal number of wheels. Ten years ago there were few cars of greater capacity than 30 tons, and now 50 tons of coal and ore are quite common. These high capacity cars generally have steel frames and weigh little more empty than the 30 ton cars with wooden frames of previous years. The draft gear is of course very much more heavily strained than formerly, as the first car in the train must take the total pull of the one or more locomotives at the head of the train; this has led to the introduction of friction draft gears instead of entire dependence upon springs. The steel sills are much better able to stand the heavy pulling and buffing strains than the old time wooden sills and while the cost is considerably greater (about \$200 or \$300 per car) the evidence at this time indicates a much longer life and usefulness for the steel cars and a decreased cost of repairs.

G. R. HENDERSON,

Author 'Locomotive Operation.'

Railway Heavy Passenger Trains. Like everything else in railroading the heavy passenger train of to-day is a creature of evolution. Heavy long-distance trains were an impossibility before the development of safety appliances and the inventions of Westinghouse and Pullman and before the consolidation of connecting lines had proceeded to a sufficient extent to permit of the passage of trains for many hundreds of miles over tracks under one management. Friendly co-operation between connecting lines, indeed, is the distinguishing feature of these famous trains.

The "Flying Yankee," one of the first of these trains, beginning service in 1884 between Saint John and Boston, is still in service. It consists regularly of ten cars, all vesteded, and uses the tracks of three railroad companies to

accomplish its daily journey. The Cleveland, Cincinnati, Chicago and St. Louis, better known as the Big Four Route, sends its Florida Special from Chicago and Cleveland to Saint Augustine, and claims patronage on the ground that the traveler is but one night out from Chicago. This train is taken up by the Queen and Crescent Route at Cincinnati, the Southern Railway at Chattanooga, and the Florida East Coast Railway at Jacksonville. Another heavy long-distance train is the Washington and Southwestern Limited of the Southern Railway. It has been operated in daily service for fifteen years. Using the Pennsylvania Railroad from New York to Washington, the Southern Railway takes the train in charge to Atlanta over its own tracks. Here the Atlanta and West Point and the Western Railway of Alabama are called into service for the journey to Montgomery, and from this point to its final stopping place—New Orleans—the Louisville and Nashville is used. The equipment is exclusively of high grade, heavy Pullman standard, including club and smoking cars, drawing-room sleeping cars and observation-library cars, besides a heavy dining car.

A notable instance of co-operation in through service of heavy trains is furnished by the Missouri Pacific, the Iron Mountain, the Texas and Pacific, the International and Great Northern, and the National Lines of Mexico, in the recent establishment of the Mexico-Saint Louis Special. This train leaves Saint Louis semi-weekly on Tuesdays and Fridays, and occupies fifty-five hours in the journey to the City of Mexico. No higher grade of service has ever been attained between this country and Mexico than is that of this solid vestibuled train. See RAILWAY SYSTEMS and RAILWAY TRAFFIC.

Railway Hospitals, in the United States. When the question of hospital relief of the railway employees of this country is compared with other countries, particularly the European, the investigator will be surprised and shocked to find how inadequate and inferior are the provisions made in the United States, in comparison to those in Russia, Germany, France, England and other countries. W. H. Ballou writing on this subject, says:

It is to be regretted that the story of the injured American railway employee is not wholly flattering to this nation, and that to tell it truthfully, even with its hopeful features, followed by the story of the Russian railway employee, must necessarily redound to the glory of Russia. Incapacitate a Russian railroad man, however high or humble, and he and his family become wards of the government so long as they live. The American railway employee often has only his brotherhood or labor organization on which he can rely somewhat in case of death or accident. Apparently there is nothing for his family except his small savings, if any, and his small share of a brotherhood or association insurance fund, excepting on a few lines. In case of his death, his family must practically become their own bread winners. If he is maimed, he is probably taken to the nearest public hospital, if in a populous district, or he may be thrown on the liberality of the nearest farm-house and country doctor. If incapacitated for life he often becomes an object of charity; or if arrangements can be made for his care at a very small cost his brotherhood and the several organizations to which he belongs assess themselves for his maintenance. What to do with incapacitated employees has ever been a problem for the railway man.

It cannot be stated that this subject has not received thorough investigation. No subject in connection with railway management has been

any more thoroughly and intellectually studied. The conditions existing in this country are so radically different from those existing in European countries, as to make it a problem in political economy far-reaching and excessively difficult of solution. Charles Francis Adams, Dr. W. T. Bernard, W. T. Kirkman, Samuel R. Barry, K. H. Wade, R. F. Smith, and a host of others, have studied this question and written extensively. It is to be deplored that neither productive co-operation, nor profit-sharing plans have demonstrated their practicability and magnificent effects in influencing industrial interests. It is reasonable to believe that all earnest, sensible men, be they the chief executives of large industries or not, would hail with pleasure any solution to the labor question.

It will be manifest to the most casual investigator that the advancement in relief measures in this country is slow and halting, but while various forms of relief measures are far behind the European countries, it is an undoubted fact that no form of labor as a mass is as highly paid as railway labor is in this country; the wages paid to the railway employee would be sumptuous pay for many professional men in Europe. The Interstate Commerce Commission states that 60 out of 350 railway companies have an insurance or guaranty fund, or hospital fund, or relief association affording aid in various degrees to employees, or both co-operating on some mutual plan, 13 companies make distinct provision for superannuated employees when disabled by accident; 125 companies give preference to employment for service for which they are qualified, or provide in divers ways and degrees during disability at the companies' expense; 225 do not.

The hospital departments differ from relief associations in the fact that the relief departments are essentially insurance companies insuring the sick and injured employees for loss of time in sickness, and injury and death benefits to family. The rate of assessments in relief associations ranges from 75 cents to \$3.75 a month. We will name only the best form of relief associations, as being those of the Pennsylvania Railroad Company, the Baltimore & Ohio, the Chicago, Burlington & Quincy, and the Delaware, Lackawanna & Western, while the Northern Pacific Company has a mixed hospital department and relief association. The Pennsylvania Railroad Relief Association and the Baltimore & Ohio have had pension features operative. Hospital departments differ from relief associations in the fact that an employee signing the application for membership in a relief association signs away his rights as a litigant for injuries received, and accepts in lieu thereof sick, injury, pension and death benefits. Membership in hospital departments have no connection with the future litigation of an injured employee. The average rate of assessments in hospital departments are 25c and 50c monthly. For the assessment the hospital department gives treatment for all diseases (except those arising from vicious acts), and for all injuries. The monthly assessment is contributed for the purpose of sustaining the hospital department. All compensations for injuries received are settled for by the companies according to legal merit in each case through claim and legal departments.

RAILWAY HOSPITALS

Hospital departments upon railroads in the United States were established as a matter of necessity and economy, as railways were built and extended over trackless plains or among tortuous passes and cañons of mountain ranges, in thinly peopled regions, and it was at times utterly impossible to obtain medical relief. It soon became demonstrated that the indiscriminate employment of medical men whose sympathy and warped judgment when treating either injured railway passengers or employees made prejudiced and unjust witnesses in case of litigation, and thus became extravagant factors. Again, it was shown that a trained corps of experienced surgeons when employed by the railway companies were enabled (owing to extended experience and consequent education), to be more competent to obtain better results in the treatment of these (railway) injuries than the inexperienced and imperfectly trained. The first hospital department organized upon any railway in the United States possessing the characteristics of hospital department as now organized, was developed by the late Col. A. N. Towne, second vice-president and general manager of the Southern Pacific Railway. This hospital department was organized in California in 1868, and was at first maintained by voluntary assessments, but this form of assessment not being self-sustaining, the assessments were made obligatory upon each and every employee of the Southern Pacific. It was not until 11 years after that the Missouri Pacific Company organized its hospital department, shortly after the late Jay Gould began the formation of the Missouri Pacific system. As each new road was added the hospital department extended over it. The Missouri Pacific system then included the Missouri Pacific Company and branches, the Missouri, Kansas & Texas, the Saint Louis, Iron Mountain & Southern, the Texas & Pacific, the International & Great Northern, the Wabash East and the Wabash West. Afterward the Atchison, Topeka & Santa Fé, the Gulf, Colorado & Santa Fé of Texas were started, and at the present time there are 17 companies having organized hospital departments, treating annually over 268,000 patients.

In the formation of hospital departments, the circular issued by the management of the railway constitutes the source and directions for collecting deductions to constitute a hospital fund. It is not necessary to give the rules in full, but the following will answer:

1. On wages earned of \$50.00 and over per month a deduction of 50 cents shall be made. On wages earned of under \$50.00, a deduction of 25 cents shall be made.
2. No deduction will be made when the amount earned is less than \$1.35 in any one month.
3. Any employee who may be taken sick shall be entitled to admission to the hospital upon presentation of certificate signed by his (or her) foreman, approved by the head of that department of the company's service.
4. Patients received at the hospitals and emergency stations will be provided by the institution with everything necessary to their careful and comfortable treatment, so long as they obey the rules established for their protection and require the professional service of a surgeon or physician.
5. Any employee receiving a certificate of disability, signed and approved as above, will be entitled to receive from the head of his department a pass to the hospital from any point on the line.

Local surgeons are appointed along the line ranging from 30 to 50 miles apart. All local

surgeons are under contract, and the fee bill for services is contained in the contract. The following explains the manner in which accidents are cared for:

INSTRUCTIONS TO EMPLOYEES AND OTHERS FOR THEIR GUIDANCE IN CASES OF ACCIDENT RESULTING IN PERSONAL INJURY.

1. All cases of accident where an employee or other person is injured, notify at once the chief surgeon of the same, and place the injured person in the care of the nearest division surgeon or local surgeon as soon as possible.
2. When the injured person is able to be moved take or send him to the nearest division surgeon or local surgeon in the direction in which the first train is going, notify the local surgeon by wire of his coming and the character of his injury.
3. In case the injured party cannot be moved, place him in the care of the nearest local agent, who will take charge of him, and notify at once the nearest division or local surgeon.
4. No surgical operation shall be performed until the arrival of the division surgeon or local surgeon, unless it may be required for the immediate safety of the patient.
5. In cases of accident, when a number of persons are injured, procure at once the services of competent surgeons in the immediate vicinity and give every attention and care to the wants of the injured. Notify division or local surgeon in each direction and the chief officers of the road by wire, giving particulars, number injured, and what is required for their relief.
6. Tramps, children, and other persons not employees, injured by their own carelessness, in jumping on or off trains, must be sent to their homes, or placed in charge of local relief authorities.
7. In case of injury resulting in death of party, notify coroner at once, and await the direction of the chief surgeon as regards disposition of remains.
8. Stretchers for the convenience of injured and sick are to be found on all train baggage cars, and at all points where local surgeons are stationed.

INSTRUCTIONS IN CASE OF SICK EMPLOYEES.

1. Sick employees desiring hospital benefits must procure from their foreman certificates (furnished them for this purpose) which when presented at either of the above-mentioned hospitals, will entitle them to admission or treatment, as they may desire, except chronic disease and those arising from vicious acts.
2. Employees desiring medicine can apply for the same at hospital and emergency stations. These applications for medicine must be signed by the foreman, otherwise they will not receive attention.
3. Passes will be supplied all employees by heads of departments for transportation to the various hospitals. In case of emergency when delay would arise in procuring a pass, notify chief surgeon by wire, and transportation will be arranged at once.
4. Applications for medicines should be addressed to chief surgeon.

The hospital fund being now established, chief surgeon, division surgeons and local surgeons appointed, local surgeons' reports furnished and various forms needed supplied. In the start of any hospital department the railway company supplies the hospital; besides supplying transportation to and from the hospital or hospitals, and emergency stations. The company collects and audits and has general supervision of the hospital fund. It assumes all the responsibility in case of an inadequacy of the fund to meet all obligations brought against the hospital department. Besides having division and local surgeons in hospital department, each hospital in the department has a competent corps of surgeons, from two to five hospital internes, all necessary specialists, such as the oculist, the aurist, throat and lung specialist, the dermatologist, neurologist, and the bacteriologist. The specialists employed upon the hospital staff are generally medical men of high reputation. Prescriptions are filled and sent out to any employee making proper application. Trusses, elastic bandages, various minor prothetic agents, are sent when requested. Large systems like the

RAILWAY HOSPITALS

Atchison, Topeka & Santa Fé, the Southern Pacific, and the Missouri Pacific, having more than one hospital situated in different regions of country, are enabled to make an interchange of patients where climate may be beneficial. The consumptives sent to climates having favorable surroundings and proper altitude. Employees suffering from catarrhal and rheumatic troubles are sent to hospitals built in the warm regions of the South. This interchange of patients cost the sick railway employee nothing but the small sum of money used in buying sustenance from one point to another. Where prominent watering places such as Hot Springs are on the line of road, local surgeons are stationed for the purpose of treating sick employees.

The benefits of the hospital department having broadened out in every direction for the benefit of the sick and injured employee, the most casual investigation will show that these departments are all well patronized. In the matter of sanitation and hygiene, these departments have been very efficient and useful, issuing from time to time circulars for the guidance of the employee during the prevalence of epidemic or endemic trouble; also in investigation of the sanitary condition of depots, shops, and section houses, and doubtful water supply. At this juncture a description of the manner in which the larger hospital departments and associations are administered, there being differences concerning the benefits obtained by the employee and the form of government controlling the collected hospital or association fund.

The Southern Pacific Hospital Department has one general hospital in San Francisco, Cal., costing \$160,000, besides having six division hospitals, and nine emergency stations. These hospitals and emergency stations in 1903 treated 58,220 patients; 3,395 were in-patients, the balance were out-patients. This department gives the following benefits: hospital treatment, medical and surgical outside of hospitals, medical and surgical dressings, artificial limbs and appliances, accommodations at railway and contract hospitals for dependent members' families. The government of the hospital fund is by the general officers and chief surgeon of the Southern Pacific Company.

The Missouri Pacific Hospital Department is governed by the vice-president, general manager and chief surgeon, and has one general hospital in Saint Louis, costing \$110,000, one division hospital, 12 emergency stations, with six contract hospitals. It has the following benefits: medical and surgical treatment at hospitals and emergency stations; supplies surgical dressings, prescriptions sent out on road, also supplies mechanical appliances, trusses, artificial eyes, and various minor prosthetic agents; carries out interchange of patients from one hospital to another, requiring climatic treatment for sick employees, issues when needed to the employee hygienic and sanitary circulars, and supplying coffin and shroud for dead employees. Total number of patients treated 42,084.—In-patients, 8,615; out-patients, 33,469.

The Atchison, Topeka & Santa Fé Hospital Association is governed by the Atchison, Topeka & Santa Fé employees, electing annually a board of control and the chief surgeon. This association has five new and modern hospitals; the Topeka hospital costing nearly \$100,000. All

of these hospitals are owned by the hospital association. There are two emergency stations at Denver and Chicago. It supplies surgical dressings, artificial limbs, trusses and mechanical appliances, medical treatment extended to employees along the line of railway and hospital benefits at all of the hospitals; likewise, interchange of patients for troubles benefited by climate. Total number of patients treated by this association: surgical cases, 4,898; medical cases, 34,273. Total from all sources, 39,171.

The Northern Pacific Beneficial Association of the Northern Pacific Company, is governed by Hospital board elected annually, and has two general hospitals, two division hospitals, and six emergency stations. It has essentially the same benefits as the Atchison, Topeka & Santa Fé Hospital Association and the Southern Pacific. It treated 33,375 patients during 1903.

The Wabash Employee Hospital Association of the Wabash Railroad Company, has three division hospitals and 11 emergency stations. The benefits are the same as the Missouri Pacific Hospital Department. It treated in 1903, 3,151 surgical cases, 22,865 medical cases; total, 26,016.

The Saint Louis & San Francisco Hospital Association, governed by Employees' Hospital Association, has one general hospital and 15 emergency stations. In 1903 it treated 11,573 medical patients, 4,852 surgical patients. Total treated, 16,425.

The Denver & Rio Grande Medical Department, governed by the Board of Employees. The benefits are the same as Missouri Pacific Railway Hospital Department. Has one general hospital, 12 emergency hospitals. It treated in 1903, from all sources, 15,581 cases.

The Saint Louis Southwestern Medical Department is governed by general officers and chief surgeon, and has two hospitals. The benefits are the same as the D. & R. G. It treated in 1903, from all sources, 13,809 patients.

The Missouri, Kansas & Texas Hospital Department is governed by the general officers and the chief surgeon, and has one general hospital and nine emergency hospitals. The benefits are the same as the Missouri Pacific Hospital Department. Treated in 1903, from all sources, 9,876 patients.

The Texas Midland Hospital Department, International & Great Northern Hospital Department, Gulf, Colorado & Santa Fé Hospital Association, and the Chesapeake & Ohio Hospital Department have eight hospitals, treating annually nearly 19,726 patients. The benefits are the same as Saint Louis & Southwestern. Hospital departments upon railways enable the employee belonging to these departments to obtain compensation for personal injuries and permanent disability far in excess of what the employee could possibly obtain when working upon a railway not having hospital department. Labor organizations predominate upon Western systems. Each branch of service has its own labor organization. Thus the engineer belongs to the Brotherhood of Locomotive Engineers; the conductor to the Order of Railway Conductors; the fireman to the Brotherhood of Locomotive Firemen; the brakeman and switchman belong to the Brotherhood of Railway Trainmen, etc. Each of these orders has its own insurance features, the orders aiming to become thoroughly

RAILWAY INTERCHANGE CAR-SERVICE

protective, sustaining their members when in enforced idleness, ensures them against permanent disability, and members' families by payment of death benefits. Suppose that a locomotive engineer has been permanently disabled, he at the time of his permanent disability is employed upon a railway having a completely equipped hospital department. He is treated free of charge from a year to a year and a half and more, that is, until well. During the time the employee is disabled he is supplied with all necessary medical and surgical treatment, for which he has paid 50 cents a month, or \$6 a year, getting a return for this several hundred fold of that which he has contributed. Had this employee been compelled to pay for treatment, it can be readily seen what doctor, board, nurse and other bills would amount to. Perhaps this same workman has not accumulated in the interim of his labor enough means to stand the expense, still he receives this treatment in virtue of the fact that he has paid his assessment to the Hospital fund, which justly entitles him to the treatment received, and is in no sense dependent upon charity. Again, let it be understood, that this same injured man is a member of the relief feature of the association of the Brotherhood of Locomotive Engineers. He gets from this source from \$1,500 to \$4,500 for permanent disability. In addition to this there is left to him what he may get from the railway company for the settlement of his claim. If he has been provident, as a good many are, he may hold one or more policies from one of the regular accident insurance companies. The money he receives from his order enables him to take care of his family while he is laid up in process of treatment. It is not a remarkably infrequent thing for a permanently disabled employee to obtain from \$2,000 to \$10,000, and in addition thereto receive from the company employment such as he can do in his crippled condition. It will thus be seen that many seemingly harsh emergencies are successfully met, accorded the best of medical and surgical treatment, supplied with every element required, obtains means to support his family while not earning, and afterward frequently placed in a position where he is still competent to become a bread-winner, though in a disabled condition. In England many employees are contented with \$500 for permanent disability. With organized labor and a hospital department it is certainly in many instances a most perfect safeguard of the interests of the employee, not only immediate, but future.

It has been demonstrated that while the surgery of railways may in many respects resemble other violent forms of surgery still an extended experience is required in order to be enabled to accomplish the best results, so that it can be readily seen that the surgery of the present demands certain conditions which cannot be readily obtained outside of a hospital. So that, if the result is to be considered, whatever hardship may be imagined as far as treatment at a hospital is concerned, its benefits are worthy of the sacrifice. Secondly, owing to the excessive breadth of medicine, owing to the fact of its constant improvement, it is an utter impossibility for one man even to have a meagre knowledge of the entire field of medicine. Specialism has demonstrated that competency only comes from study and experience, and the results obtained

by specialism have been marked and pronounced. Hence, in well regulated hospital departments every necessary specialty is employed, the oculist, the aurist, the dermatologist, the throat and lung specialist, the neurologist, so that for the \$3 and \$6 a year the employee has the advantage of consulting and receiving treatment from all these various forms of specialties, without any additional expense. Surely this is broad enough when the small sum is considered, namely the \$3 and \$6 per year paid in assessments. Again, they enable the employee to be removed from unhealthy regions to more healthy ones. The management furnishes passes to and from any part of the line as deemed best by the surgeons in charge of its hospitals and emergency stations, and employees are thus brought to hospitals from malarial portions of the country to non-malarial, and it is possible for the humblest employee to change from bad to more healthy and salubrious climes. The hospital department is thus enabled to effect cures by the fact of this change which otherwise could not be accomplished; besides they are enabled to send the consumptive to climes better fitted for his treatment and care which a lack of means on the part of the employee would oftentimes debar. See HOSPITALS.

DR. W. B. OUTTEN,
Chief Surgeon Missouri Pacific Railway Company.

Railway Interchange Car-Service. Whenever traffic demands it, and physical and political connections allow it, cars are interchanged between railways. The arrangements under which these interchanges are made vary, but they are always intended in some sort to compensate the car owner for the use of his property and usually to secure its return. Some of these arrangements, therefore, are based upon the distance traveled by the car upon foreign rails, others upon the time the car is away from home, while others yet are "mixed systems" combining the bases of distance and time. It is to be noticed that where the interchanges are most general the arrangements are the simplest. Thus, in Europe where mixed systems prevail the interchange of freight cars is not so general as in North America where a simple system based on time is in effect. Again, in North America the interchange of passenger cars, which involves a prior agreement as to whether the basis of compensation shall be time or distance, is not so general as the interchange of freight cars, which is covered by this general and simple agreement. The agreements and arrangements covering the interchange of cars are made in some cases between two railways, in others by associations of railways, and in other cases by governments. Thus, on the continent of Europe interchanges are arranged by the government involved, in England by the Railroad Clearing House and in North America by the American Railway Association.

In Europe and Asia it is quite general to make a certain charge per mile for the use of foreign cars on the understanding that a certain time will be allowed for a journey of a certain length. If the car is delayed beyond the time allowed, a demurrage charge is imposed besides the mileage. The various systems in vogue are of a certain complication involving a separate calculation for each car, and in some cases more

RAILWAY INTERCHANGE CAR-SERVICE

than one calculation. In America, on the other hand, the tendency has always been toward simplicity, even when this sacrificed more essential conditions. In the interchange of passenger cars the interest of the car owner has always been conserved, but in the interchange of freight cars, until a comparatively recent date, the interests of the car owner were sacrificed in the interest of a faulty simplicity. Since the middle of 1892, however, a marked improvement has been made, and the car owner is now sure of a certain compensation for every day his car is on a foreign railway.

The value and scarcity of passenger cars has always made railways conservative in their interchange. When two or more lines regularly interchange passenger cars in America in "through service" it has been quite general to equalize the mileage so far as may be by manipulation of equipment, so that the mileage balance could be made as small as possible, and this mileage balance has generally been settled on the basis recommended by the American Railway Association, which includes in its membership all of the prominent railways of North America. These mileage rates are as follows:

| | |
|--------------------|------------------------------|
| Coaches, etc. | Three cents per mile. |
| Baggage cars, etc. | One one-half cents per mile. |

In cases where passenger cars are loaned temporarily it has been more usual to apply the "Per Diem" rates recommended by the same body, namely:

| | |
|--------------------|--------------|
| Coaches, etc. | \$5 per day. |
| Baggage cars, etc. | \$3 per day. |

With freight cars the case is different. The American Railway Association having adopted a set of "Per Diem Rules Governing Settlement for the Use of Freight Cars," in April, 1902, the railways of North America, with few and unimportant exceptions, signed an agreement that they would abide by these rules for the space of one year and thereafter upon three months' notice. This agreement has now been in effect nearly two years with slight amendments in the rules, and there is every indication that the arrangement will be a permanent one. The claim is made, with some show of justice, that this agreement of 551 railways, representing a capital of over \$13,000,000,000, if not the most important, is certainly the most far-reaching agreement ever signed. The rules covered by this agreement provide for a uniform payment of 20 cents a day for each car. If any road holds a car more than 30 days, the owner upon due notice, can increase this rate to a dollar a day, thus putting into effect what is called the penalty rate. There are rules also which provide a certain relief for belt lines, rules providing for the necessary accounting features, for embargoes and for the arbitrating of differences.

Up to 1902 the arrangements for the settlement of freight car interchange in North America were in a very peculiar condition. When the first American railways were built it was not supposed that they would interchange their own cars. Indeed, it was generally thought that all cars would be provided by the shippers. The first cars interchanged between railways were generally not railway cars but cars belonging to "fast freight lines," some of which were owned

by individuals and others by associations of railways. It was quite general to divide the through rates charged by these fast freight lines on a mileage basis and it was natural that the expense for cars should be divided on the same basis. The first rate generally in effect was one cent per mile, and this rate, which was primarily applicable to private line cars only, was gradually extended to such railway cars as were interchanged, the car resources of the fast freight lines proving inadequate to supply cars for the traffic offering. The first of these railway cars interchanged appear to have been sent away from home without any definite understanding either as to compensation or as to reports of movements; but, as above, the rate of one cent per mile (which was afterward reduced to three fourth of a cent and later to six mills) came into general effect, and it was arranged by the Car Accountants' Association, which represented most of the railways of the country, that a "junction report" should be sent to the owner of each car whenever it was interchanged between foreign railroads. By entering up these junction reports in their car records each railway was able to locate its cars and to trace for them either by letter or by "Car Tracers" or "Lost Car Agents," who were largely employed to secure the return of cars. For, it should be noted that this mileage system, which had been adopted for the compensation of car owners, did nothing to secure the return of cars to their owners. Indeed, it was cheaper to hold a car indefinitely than to return it, as the actual movement of a car in the direction of home cost 75 or 60 cents for every hundred miles it moved, while it cost nothing to keep it standing. Another difficulty lay in the fact that there was no effective check on the accounts rendered by each railway for the use of the cars of others, and there was some suspicion that certain mileage accounts were cut. The vices of this system were early recognized by some of the railways and in the year 1876 the Union Pacific and the Chicago, Burlington & Quincy arranged to cover their own joint interchange by a per diem payment at the rate of 50 cents per car per day. This arrangement continued in effect for a couple of years with the result that the movement of the cars covered by this arrangement was greatly expedited. There was no general agreement, however, with other railways to put this arrangement into effect and it was, therefore, discontinued. The per diem system was later called to the attention of the Car Accountants' Association by J. T. Rigney, of the Baltimore & Ohio Railway, who in 1878 read a paper before that body urging its general adoption. Mr. Rigney's efforts were followed by W. P. Shinn, who covered the system in an admirable set of papers which did a great deal to mold the opinion of railroad men on the subject.

Although the condition became worse year after year and the delays to foreign equipment became very serious, especially at terminal points where individuals without capital were encouraged by the mileage system to undertake extensive business by using railway cars as warehouses, no steps were taken toward the mitigation of the mileage system until 1888 when it was brought before the Trunk Lines, and Albert Pink formulated a set of rules covering a mixed

RAILWAY INTERCHANGE CAR-SERVICE

system, which provided for the payment of one half cent a mile and 15 cents a day for the use of cars. This plan was logical, inasmuch as the per diem rate was intended to cover the cost of depreciation and interest on investment, while the mileage rate was intended to cover repairs, but it was much more expensive in administration than the mileage rate. Unfortunately when it was adopted it was by two of the stronger lines without consultation with the rest of the country. As a result only a minority of the railways adhered to the plan and after it had been in effect for a month, there began a series of secessions of the railways which found it expensive in comparison with the mileage system. Each secession made the system more expensive to the two trunk lines which had originated the experiment and at the end of a few months the plan was definitely abandoned.

This experiment of 1888 was very expensive to some of the lines involved and the experience gained showed clearly that no experiment could succeed unless the arrangement was put into effect throughout substantially all the United States and Canada and was kept in effect until sufficient experience had been gained to warrant a change in the rules. The failure of the experiment also cast a shadow over "mixed car service systems," and subsequent movements have usually been in the direction of a straight per diem system. During the experiment of 1888 the detail of the rules was referred to the Committee on Car Service of the American Railway Association and this body has ever since had a general charge of the matter. It had early formulated a set of "Car Service Rules" which included the practice approved by the association in regard to the interchange of passenger and freight cars, but these rules although they covered fully the interchange of passenger cars and gave many particulars as to the proper handling of freight cars have always been silent as to the compensation for the use of freight cars interchanged. Rules covering per diem payments for use of freight cars were reported to the American Railway Association on several occasions by the Committee on Car Service between 1888 and 1901, but the rules were invariably referred back to the committee or tabled. Another mixed system, originated by J. M. Daly, was also tried on seven important western railways in 1898, but it lasted only a short time.

In the year 1901, however, the question was again taken up. For over a year through a remarkable revival of prosperity and expansion of industrial enterprise, there had been a marked shortage of cars on all the railways in the producing sections of the country, and these railways saw their own cars gradually leaving them only to be delayed without recourse upon foreign lines. It was by no means unusual for a railway to see half of its freight equipment and more on foreign lines, at a time when it could not fill its orders for cars. It is an open question whether the so-called "car shortage" was really a shortage of cars, a shortage of terminal facilities, a shortage of engines, a shortage of machine shops or a shortage of mechanics, but it was evident to every car owner that his cars were too long away from home, that he was not properly paid for their use, and that the foreign roads really had no incentive to return them. At

that time the rate paid per mile was six mills and the average earnings of cars on foreign lines was less than 12 cents a day. This was evidently the time for the introduction of the per diem system.

The loss to car owners in the poor movement of their cars was so evident that a group of prominent financiers commissioned J. W. Midgley to investigate and report upon the question. This gentleman's prior experience had been chiefly with the traffic and financial sides of railways, but in the investigation which he made of the subject he speedily recognized the advantages of a per diem system, which he pointed out in a series of forcible reports to the subscribers to his bureau, which were widely studied by the executive and operating officers of railways. These papers gave in great detail the history of the per diem movement and strongly urged the adoption of a per diem system, but, Mr. Midgley wisely confined his efforts to the awakening of interest in the matter and did not attempt to formulate a working plan. It was during this revival of interest in the subject that the American Railway Association met at Saint Louis in October 1901. The matter was carefully canvassed in the association and the last report of the Committee on Car Service was taken from the table and referred back with instructions to prepare a practical scheme for the introduction of the per diem system. This action was taken without opposition, as the railways which were profiting by the mileage system did not apparently realize the decided feeling on the subject and the far-reaching character of the instructions given the committee. For the next six months the Committee on Car Service was busily occupied in formulating a set of rules for the per diem system, in which they were aided by a large majority of the roads in the country. The circulars of the committee, asking for information, were answered fully and carefully and the committee in its deliberations was, therefore, guided by the views of practically all the men in the country who had experience in car service matters. At the same time the opposition began to crystallize. A per diem plan, such as had been heretofore presented, was most objectionable, first, to the belt railways, which had never paid any mileage at all; second, to all the short railways, which made a small mileage per day on foreign cars; and third, to certain private owners of cars, and especially of refrigerator and stock cars, which, for traffic reasons, were moved on fast freight trains and which made high mileage per day. Many of these private parties were also interested in railroads and it was felt their opposition might seriously complicate the adoption of the per diem system.

The first duty of the committee, was, of course, to construct a workable system, and in this they were aided greatly by the experience gained in 1888. The car accounting features of the rules as decided upon, presented, therefore, no marked innovation and have worked without friction. Prior schemes had not, however, provided for the settlement of differences of opinion in regard to the rule or any continuity of the arrangement. These points were covered by arranging for an arbitration committee and also for a per diem agreement to be signed by the railways participating. Having arranged a

scheme which would be workable generally, it was necessary for the committee to provide for certain exceptional cases. This it did by arranging that the per diem should be regularly reported at the end of every month and exceptions should be covered later by a system of what they term "reclaims," the word reclaim being adopted instead of refund, or some more usual term, in order to separate the reclaim payments from all others. It was felt that the circumstances in different parts of the country so varied that no central body could settle exactly what would be a fair reclaim for cars in switching service on belt roads, but it was decided that any reclaim that was made should be an arbitrary amount per car, so as to preserve the incentive for prompt movement. It was also provided that the per diem on cars refused at interchange points should be covered by reclaim and provision was made for special reclaim covering special circumstances.

It then remained for the committee to figure out a per diem rate which could be accepted in all parts of the country and here they were urged on one side to make the rate as low as 12½ cents a day and on the other, to make it as high as one cent per ton capacity. A compromise rate was the only one that could be generally accepted, and the committee finally advised a 20 cent rate, with the proviso that in case a car was delayed on any one line longer than 30 days, a penalty rate of \$1 could be imposed in lieu of the per diem rate. The opposition of private car owners was obviated by leaving private cars entirely out of the question and providing that per diem rules covered railway cars only.

With this scheme worked out the committee reported to the American Railway Association at its meeting in New York in April 1902, where the rules were debated in full and the liveliest opposition encountered on the part of advocates of mileage, of low rates, and of high rates. The rules, however, were adopted by the association by a large majority and it was agreed to put the plan into effect on 1 July 1902, provided that the agreement was signed by a majority of the whole membership of the association and provided that that majority owned 66 per cent of the cars owned by all the members of the association. The agreement was promptly circulated among the railways of the country at large and the secretary of the association was able to announce in a comparatively short time that the agreement had been signed by the desired number of members. There was some opposition on the part of a comparatively small number of roads in the East who attempted to make an exception of cars loaded with cotton, but this was promptly settled by the withdrawal by the per diem railways of all through rates on cotton to the territory in question, a stroke which led to an immediate adhesion to the per diem plan of practically all dissenters.

This plan has now been in effect for about two years and while there are still certain difficulties in its administration there seems to be no prospect of a departure from the general per diem principle. Indeed, there is a strong movement in the direction of applying the principle to private cars. It was anticipated when these rules went into effect that there would be con-

stant litigation under them, but the fact that there have been only 16 cases decided by the Arbitration Committee shows that the rules are generally satisfactory. To be sure, a number of the larger car owners are still pressing for a higher rate and an abolition of the penalty which will possibly be arranged in time, and a number of industrial railways are endeavoring to enter the scheme because of the very liberal reclaim allowed on switched cars. Again, there is a disposition shown on the part of some of the larger systems to divide themselves for car accounting purposes in order to avoid the penalty rate, but none of the difficulties involved appear to be radical or to approach in magnitude the radical difficulties of the past mileage systems. It is thought, therefore, by a careful revision of the rules from time to time the per diem system can be maintained and its efficiency improved.

ARTHUR HALE,
Gen. Supt. Transportation Baltimore & Ohio
Railroad Co.

Railway, Intercontinental, or Pan-American, a proposed railway system extending from the United States through Mexico and the Central American states to Panama, and thence southward to Brazil. The Intercontinental Railroad Commission was organized in Washington in 1889 to study the feasibility of extending a trunk railway from our country to Buenos Ayres. The report of the commission on its studies and its surveys for the best route was published in 1899. The proposed all-rail route to Buenos Ayres will be 10,228 miles long by the route which the surveyors selected. In 1900 the existing lines that might be used as a part of the trunk railway were about 4,772 miles in length, leaving 5,456 miles to be constructed. Since that time the Latin-American countries have built 656 miles of track along the international route, reducing the portion yet to be constructed to 4,800 miles. Only about an eighth of the mileage has been built since 1900, but this has been done in the natural course of railway building without any reference to the Intercontinental project. The estimated cost of construction for the 4,800 miles is placed at \$150,000,000. This is based on an average of 50 cents gold as the daily wage labor, with an efficiency of 75 per cent as compared with similar labor in the United States.

Railway Labor Organizations, labor unions formed by the employees of railways to advance their interests and promote their social, moral, and intellectual welfare. The larger and more typical railway labor organizations are distinguished for their generally conservative attitude, their large mutual benefit and insurance funds, and their organization of grievance committees for arranging differences between their members and employers, and avoiding strikes. As a rule they maintain pleasant relations with employers, and have been instrumental in obtaining increased wages and general improvement in the condition of railway labor. The five most prominent organizations are the Grand International Brotherhood of Locomotive Engineers, the Order of Railroad Conductors, the Brotherhood of Locomotive Firemen, the Brotherhood of Railway Trainmen, and the Order of Railroad Telegraphers. These five have the same general form of organization, with

RAILWAY LABOR ORGANIZATIONS

the supreme power in the central representative body called the Grand Lodge or Grand Division, meeting in convention every two years, and the executive power vested in a chief executive (Grand Master or Grand President) and an executive board. Their subordinate divisions include locals and section divisions, the latter made up of the employees of one railway line or system. Their provisions for dealing with grievances against employers are as follows: Any member or members having a grievance against an employer are to report the same to their local organization, which, in case the majority vote to sustain the grievance, shall refer it to a local grievance committee. This committee is to deal with the local management, and should no satisfactory settlement be made, refer the grievance to the General Grievance Committee of the section, who shall confer with the general manager of the railway system. Then, if no adjustment be made, the matter is to be referred to the chief executive of the union who shall make another attempt to adjust the matter with the employers, and, if he fail, he and the General Committee shall have power to sanction a strike, provided a strike is agreed upon by two thirds of the members involved. In some cases a board of adjustment is formed by the chairmen of three or more general committees, in which case the matter is to be referred to this board before going to the chief executive. It will be seen that this arrangement makes a strike difficult to bring about, and prevents strikes for trivial causes, yet all of these unions have established large protective or strike funds for the benefit of members when on strike. Another feature of these organizations is the Legislative Board, organized in each State by representatives from each local for the consideration of questions of legislation affecting their unions; and these boards have power to appoint one or two members to remain at the State capital for securing desired legislation.

The Five Larger Brotherhoods.—(1) The Brotherhood of Locomotive Engineers was organized in 1863. The locals have sick and death benefit funds, and the Brotherhood has a fund for pensioning widows and children of the deceased. The insurance is under the management of an affiliated organization known as the Locomotive Engineers Mutual Life and Accident Insurance Association. In 1903 the brotherhood numbered 42,000 members in 596 locals. The official journal is the 'Journal of the Brotherhood of Locomotive Engineers,' published monthly. It ranks among the most important and influential labor organizations of the United States and is noted for its conservatism. (2) The Order of Railway Conductors was organized in 1868 as the Conductors' Brotherhood, was threatened with serious difficulty on account of its prohibition of strikes, and a rival union started which had a "protective" policy, the Order adopted the same policy, established its "protective" fund, and the two organizations were united under the present name. It has a mutual benefit fund, and the strike fund provides for the payment of \$50 per month to strikers for not over three months. The official journal is the 'Railway Conductor,' published monthly. In 1904 the membership was 32,000 in 454 locals. (3) The Brotherhood of

Locomotive Firemen was organized in 1873, was involved in the great strike of 1877 and seriously crippled; for a time it adopted the policy of "ignoring" strikes, but in 1885 returned to its original policy and methods in dealing with strikes; and a few years later conducted a large strike on the Chicago, Burlington & Quincy Railroad. Strikers are paid \$25 per month for three months or less. The official journal is the 'Locomotive Firemen's Magazine.' The membership in 1904 was 51,356 in 656 locals. (4) The Brotherhood of Railroad Trainmen was organized in September 1883, and admits to membership conductors, baggagemen, yardmasters, and switchmen beside trainmen. They have a sick and death benefit fund, and a strike fund, providing for a payment of \$35 per month to strikers for three months or less. In 1904 it had 68,158 members in 699 locals; its official organ is the 'Railroad Trainmen's Journal.' (5) The Order of Railroad Telegraphers was organized in 1886; its membership includes telegraphers, line repairers, levermen, and interlockers. Its mutual benefit fund was established in 1898; it has never held quite the same position of importance as the other four brotherhoods, as at the first it grew more slowly because the telegraphers are scattered, and it is difficult to get any number together, but since 1900 has grown rapidly. In 1903 it numbered 30,000; its official journal is the 'Railroad Telegrapher.'

The Union of All Railway Employees.—Though these brotherhoods have much in common in organization and purpose there has been rivalry and discord among them, which has proved decidedly detrimental to their best interests. In 1895 an alliance between the five brotherhoods was formed, providing for the formation of a Federated Board of Adjustment for the consideration of grievances and management of strikes. A more centralized Federation was organized in 1898, but dissolved in 1900, leaving the agreement of 1895 in force. The first attempt to form a union which should unite in one organization all classes of railway employees was the American Railway Union, organized in the early part of 1893 by Eugene Victor Debs. This union lacked the complicated organization of the older brotherhoods, was radical and aggressive, and met with bitter opposition from the older unions. It drew away some of their membership and grew rapidly; before the close of the year it conducted successfully a strike against the Great Northern Railroad. In 1894 it inaugurated a sympathetic strike in behalf of the Pullman Car Company employees, was defeated, and shortly afterward the organization dissolved. A later attempt to unite all railway employees is the United Brotherhood of Railway Employees, organized in January 1901. It resembles the older brotherhoods in its organization and its mutual benefit department, but differs from them in its opposition to separate trade organization, and in its radical policy, being affiliated with the American Labor Union, which is avowedly socialistic. The chief strength of this Brotherhood is in the Western States.

Lesser Organizations.—Of the smaller organizations those which closely resemble the five larger brotherhoods in organization are: (1) The International Brotherhood of Main-

RAILWAY LOCOMOTIVE REPAIRS

tenance-of-Way Employees, organized in 1887 as the Brotherhood of Railway Trackmen; its membership includes those employed in track, bridge, and building, water supply and fuel departments, and signal and interlocking service; it has a mutual benefit department, and the same provisions for preventing strikes and dealing with grievances as the other brotherhoods; the official journal is the 'Advance Advocate'; the membership in 1903 was over 10,000. (2) The Switchmen's Union of North America, organized in 1894, admits to membership those engaged in making up and disposing of trains. It has a beneficiary department, membership in which is compulsory for those physically sound. The organization is the same as in the other brotherhoods. The membership in 1904 was 23,000; this is less than it would otherwise be because of the fact that the Brotherhood of Railroad Trainmen, an older and more powerful organization, also admits switchmen. The official organ is the 'Journal of the Switchmen's Union.' (3) The Brotherhood of Railway Carmen, organized in 1900 by a consolidation of the Brotherhood Car Repairers of North America and the Carmen's Mutual Aid Association. Its membership consists of those who are employed in oiling, repairing, inspecting, and cleaning cars; it is a comparatively unimportant organization. (4) The National Railways Clerks' Association, organized in 1901, had in 1903 a membership of 4,000 in 35 locals; it publishes the 'Official Journal of the N. R. C. A.' (5) The International Association of Car Workers, organized in 1901, includes in its membership those employed in the construction and maintenance of all cars; it has no benefit department, but the arrangement for dealing with grievances and strikes by local and general grievance committees; its declaration of principles is conservative, including opposition to prison contract labor, and a declaration in favor of reduction of hours of work, and compulsory education. Its official journal is the 'Car Worker'; its membership in 1903 was 20,000. Of these organizations the Brotherhood of Maintenance-of-Way Employees and the International Association of Car Workers are affiliated with the American Federation of Labor (in 1904).

There is also affiliated with the Federation another railway clerks' organization known as the International Association of Railway Clerks, organized in April 1903. Its organization differs from that of the railway brotherhoods; it has annual instead of biennial conventions, no benefit department, and no system of grievance committees; a strike, however, must be approved by the district council or international executive board.

Railway Locomotive Repairs. The average life of a locomotive between the times of receiving general repairs to flues and machinery depends chiefly on the condition of the track over which the engine works, the number of tons of freight which the engine is required to haul, and the kind of water used in the boiler. If the road pass through mountainous regions and the track has many curves, the wear on the tires and machinery is exceedingly rapid and the life of the engine will be but a few months; or if the road pass through hard water districts where the water contains much solid matter,

such as lime and other ingredients, the incrustation of these substances on the flues will soon render the engine unfit for further service on account of leaky flues and failures for steam. The length of time an engine may be kept in service will also depend on the roundhouse inspection and care given at the terminals of the divisions. Observance and attention to little things will often save a failure, maybe a wreck, on the road. The tightening of nuts and the application of cotters may save the bolt, which, if allowed to drop out, would result in serious damage to the engine. In bad water districts the boiler should be washed frequently and thoroughly so as to remove all accumulations of sediment. Careful attention to this work will add much to the life of the flues and the steaming qualities of the engine.

The following card, if properly used, will be found very effective in securing a thorough inspection at the end of each trip. The engine inspector should place a check mark on the square opposite the number of each item as he inspects that part and when the inspection has been completed any defects found should be noted on the back of the card. A work report

A. B. C. RAILROAD COMPANY

ENGINE INSPECTOR'S REPORT.

Engine No. _____

| | | Division | 190 |
|----|-------------------|----------|--------------------|
| 1 | Axles | 38 | Grab handles |

| 37 | Guides | 74 | Wheels |

should also be made out covering the defects found and turned over to the proper person to make the repairs. Before the engine leaves the terminal the inspector should again look the engine over to see that all repairs have been made. The work report and card can then be turned over to the proper authority as a matter of permanent record.

Light repairs, such as examining pistons, renewing cylinder packing rings, closing rod brasses, replacing bolts, and similar work, are usually classed under what is termed running or

RAILWAY LOCOMOTIVE REPAIRS

roundhouse repairs and are accomplished at the end of the trip before the engine is turned for further service.

When the engine has become so badly worn that a general over-hauling and renewal of parts are necessary it is then sent to the back shop for either general or certain specified repairs.

On roads having a large number of engines of different types, and a number of small shops, general or even light repairs cannot be accomplished to the best advantage unless the engines are regularly assigned to certain divisions. Where locomotives are regularly assigned to certain parts of the road, the master mechanic in charge of repairs can so arrange his stock of material as to immediately meet the requirements of the engines on his division and general repairs can be made in the shortest possible time. But where the shop manager has no means of knowing what classes of engines will be sent to his shop for repairs until he has actually received the engine, it is impossible to carry in stock the necessary parts to make quick repairs.

A report may be made by the master mechanic to the shop superintendent prior to the time of forwarding the engine, setting forth in detail what repairs will be necessary, but it will usually be found that something has been omitted and more or less delay will result. Any delay of this kind will entail a loss to the company dependent on the volume of business and variously estimated at from 10 to 25 dollars for each 24 hours the engine is out of service. Locomotive repairs are usually divided into five classes, as follows:

| | |
|------------------|------------------------|
| Class 1 repairs— | \$2,500.00 and over. |
| Class 2 repairs— | 1,500.00 to \$2,500.00 |
| Class 3 repairs— | 500.00 to 1,500.00 |
| Class 4 repairs— | 100.00 to 500.00 |
| Class 5 repairs— | 10.00 to 100.00 |

The Erecting Shop.—Work in this department should be classified and a certain part of the repairs on all engines in shop assigned to individual gang foremen. It was formerly the custom to assign each gang foreman to a certain number of pits in which case all necessary erecting shop repairs to an engine was completed by a few men. This practice is still followed in some shops to the detriment of economic operation. When workmen are regularly assigned to certain classes of repairs they become specialists and are able to accomplish the work quicker and easier than it is possible without classifications. This distribution of the erecting work should be arranged about as follows:

Gang No. 1. Stripping work, such as rods, motion work, guides, pistons, steam chests, brake rigging, injectors, pipes, pilots, cabs, frames, cylinders, trucks, etc.

Gang No. 2. Replacing frames and cylinders, chipping and filing frame jaws, fitting pedestal shoes and wedges, removing wheels and wheeling engines, overhauling and applying spring and brake rigging, trucks, etc.

Gang No. 3. Replacing all boiler mounting, overhauling pops and whistles, removing, overhauling, and replacing steam and dry pipes, laying out all new boilers for location of gauge cocks, drilling, lapping, and applying all studs in boiler, applying injectors, lubricators, etc.

Gang No. 4. Putting up all motion work, such as links and hangers, eccentrics, eccentric straps and rods, rocker boxes, reach rods, re-

verse lever, lift shaft, setting valves, lining guides, putting up valves, steam chests, pistons, etc.

Gang No. 5. Overhauling air pumps, injectors, lubricators, gauge cocks, and gauges, and all air brake attachments, and testing brakes when applied.

The Fitting Department.—This work should be under the supervision of the machine shop foreman, and should include reitting all rods, links, rocker boxes, reverse levers, pistons, crossheads, valves, and similar work. This is necessary on account of the large number of machine operations on this class of work. If the vises and machinery necessary to carry on this work are located in close range, it will enable the mechanics to work together to better advantage, and require less supervision to produce necessary results. It will also avoid trucking the parts from vise to machine and back again, and from one machine to another in different parts of the shop.

Inspection.—When an engine is sent to the back shop for general repairs it should be carefully inspected by a competent man and a condition report made to the shop superintendent. The principal features of this report should then be made out in duplicate and a copy furnished to each foreman and gang foreman in the shop so that all will be well posted as to the work required.

The Shop Foremen's Meeting.—On Friday afternoon of each week a schedule should be made out showing the number of engines to be completed the following week, and the foremen and gang foremen should be called together in a short meeting. The shop superintendent may require statements of the condition of the various departments and each locomotive on the schedule for the following week should be discussed in detail and any expected delays brought to light and accounted for. A half hour spent each week in discussing the general progress of the work in the different departments in a meeting of this kind will, in a short time, produce very gratifying results. Shop improvements, the location of tools to reduce cost of handling material, air jacks, changes in patterns to reduce the amount of machine work, or to increase the strength or wearing of parts, and many other details of the work can be talked over in these shop meetings and if suggestions are carefully carried out, it will soon result in a largely increased output of the plant.

When an engine has been carefully inspected and the foreman of the stripping gang has received a copy of the inspection referred to above, it is set in the shop over the drop pit and is ready to be stripped down.

Some shops are equipped with a drop table. The engine is run onto this table, blocked at each end and all wheels dropped at same time. In other shops a drop pit is constructed with a hydraulic hoist in the centre capable of dropping one pair of wheels at a time. In still other shops no drop pit is supplied and it is necessary to jack the engine high enough to run the wheels out. In shops of this kind, when the supply of air is sufficient, pneumatic telescope jacks should be supplied for removing wheels. The jacks can be mounted on a small pair of truck wheels and by placing two of them alternately under each end of the engine the wheels can be removed in one-half to three-quarters of an hour.

RAILWAY LOCOMOTIVE REPAIRS

In shops equipped with sufficient crane facilities, the motion work may be cut loose and the engine lifted to a permanent position before further stripping is done. No matter what method may be used to remove the wheels, the rods and attachments should be removed before the engine is put in the shop, loaded on a dummy car, cleaned, and delivered as a whole to the vise men to be refitted. If this can be done conveniently it will avoid much delay and confusion as other parts are being stripped. When the remaining parts of the engine have been stripped, they should at once be properly stencilled, cleaned, and delivered to the different departments for repairs. The card shown in the following illustration will be found very convenient in handling the work between different departments of the shop.

A. B. C. RAILROAD COMPANY

WORK REPORT

Engine No. _____ In shop _____ 190____. To be out
190____. Mr. _____ Foreman
_____ shop. Make following repairs.

When completed return card to _____

| NAME OF PART | DESCRIPTION OF WORK REQUIRED |
|--------------|------------------------------|
| | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |
| | |

Above parts delivered to _____ shop
_____ 190____. Work completed and card
delivered to _____ 190____.

NOTE:—Work on this card must be completed and ready for
delivery to _____ shop
_____ days before engine is marked for service.

This card may be used in any one of the following ways:

1. The general foreman may require each gang foreman or general work inspector to carefully inspect all parts after engine is stripped and furnish to the clerical force in his office all necessary information concerning the requirements of the engine. The cards can then be properly filled out and sent to the respective departments in which the repairs are to be made.

2. The engine being inspected and stripped in the erecting shop, the foreman of this department may require the gang foreman in charge of each class of repairs to carefully inspect his part of the work as soon as it has been removed, and report to his office the work necessary to be done, and the clerk can then make out the card and forward to the respective heads of departments.

3. The gang foreman in charge of the different classes of work may be authorized to make out cards covering the work necessary on their part of the engine and forward to the heads of other departments at the time worn or broken parts are delivered for repairs or renewal. When the parts have been fitted and are ready to apply to engine, the cards may be

returned to the gang foreman who first made them out. This will, without further notice, place him in a position to put up the work in the shortest time possible.

These cards may also be used by the machine shop foreman for work required in the blacksmith shop or by any department requiring work from some other department.

Another small card which will be found very convenient for use among different departments is shown below. This card can be used in ordering bolts, and all miscellaneous work which will necessarily be omitted from the general order for repairs, referred to above.

190____

Foreman.

Shoes and Wedges.—This is one of the most important jobs on an engine, and must receive the most careful attention as it will prevent cutting tires, breaking crank pins, and avoid much trouble with hot driving boxes and cut journals.

In filing the frame jaws much care should be exercised to see that they are made perfectly true up and down and kept square with the outside of the frame. A scraper should be used to insure a good bearing and shoes and wedges should then be carefully fitted to the jaws.

In fitting the pedestal braces the workman should be careful to see that there is no unnatural strain on the jaws of the frame, and if the braces are new they must be clamped firmly against the frame in the position which they will occupy when work is finished, and scribed for slotting. Old braces should be tried in position on the frame and if loose sent to the blacksmith shop to be closed and then refitted to frame. Thimble braces, or braces which fit between the jaws of the frame, may be lined on end if loose and refitted to jaws.

Cylinders.—In fitting new cylinders to shell of smoke box, the cylinders should be placed in proper working position and the arch allowed to rest on the saddle. Level the boiler with the cylinders. Line both cylinders and divide firebox central with lines. Drop plumb line over top of boiler and keep firebox plumb with both lines.

If the saddle will finish so as to hold the boiler the proper height, it may be laid off in this position and circle chipped to fit smoke box. If the circle of the saddle is too large for the boiler and will not true up, a piece of sheet iron or boiler plate can be used and the thickness of the same figured in laying off.

Boring Old Cylinders.—In placing the boring bar in old cylinders, be careful to set it with the counterbore of the cylinder at each end, or if back head is in place, a taper gland may be used in the stuffing box. If cylinder is badly worn, two roughing cuts will be required, and if the bar has the necessary power, the speed should be 30 to 40 feet per minute with a feed of at least $\frac{1}{8}$ inch. The finish cut can be taken with a

RAILWAY LOCOMOTIVE REPAIRS

wide nose tool at same speed but with a feed varying from $\frac{1}{2}$ to 1 inch per revolution of bar. If required, each end of cylinder should be re-counterbored with offset tool. Sometimes the tool will chatter, and this may be largely relieved by hanging a heavy weight on the back end of the bar.

Cylinders are counterbored to prevent piston from wearing a shoulder at each end, and this counterbore should extend back far enough so that the outside packing ring will just pass over the inner edge.

Rods.—The length of main rods can be obtained by placing crosshead in exact centre of guides and using a square from centre of main driving box. One end of a stick can be placed against the crosshead pin and a line scribed on back end of stick to coincide with centre of main box. Then all one-half the diameter of the crosshead pin and the result will be the proper length of the rod. In adjusting main rods to proper length, the position of the key with reference to the pin should be noted. When the key is in front of the pin, the rod is lengthened as the brass wears, and when behind the pin the rod is made shorter as the pin is driven down. The clearance, therefore, should be divided accordingly.

The length of parallel rods may be obtained by measuring from wheel centres when the wheels are under the engine. When the wheels are not under the engine, the distance between the centre of frame jaws can be measured. In either case, if the engine is cold, 1-32 inch should be allowed in length of back rod for expansion on all engines where the fire box sets down between the two back pair of wheels.

In hanging the rods, fill the wheel centres with lead, mark the exact centre of each wheel, and use tram. If the wheels are out of tram, then try the main wheel centres with centre in rocker arms, which are supposed to be right in all cases, and set shoes and wedges where needed so as to bring wheels to tram and also to keep them square with rocker boxes. When the main wheels are arranged in proper position, the others can be changed accordingly. Shoes and wedges should be set moderately tight before tramming main centres.

When pins all tram, pinch one side of engine on dead centre and put up rods on that side. Then pinch the other side the same way and hang rods. The rods should be closely lined between the pins.

In fitting the brasses to the top straps, file out top and bottom to give a good side bearing. Key the brasses up and try on pin, taking out all lost motion to prevent pounding. Rod brasses should always have a good bearing on the pin and should have a Russia iron liner between the halves before boring. They should be tightly keyed up and bored 1-32 inch larger than the pin. After they are bored, the liner should be removing before applying to pin.

Guides.—In lining four bar guides it is best to first put a centre in the crosshead and set guide gauge to it from bottom of head. The bottom guides should then be put up and cylinders lined. Always use a small line and be exact in measurements.

The guides must be kept perfectly true and level with frames across face. The crosshead should be calipered to get width between guides

and about 1-32 inch allowed for lateral motion or side play.

The guides must be divided central and kept perfectly parallel with line. A straight edge can be tried on the face of the guides and if they are out in the centre they may be sprung into place with liners.

When the bottom guides are properly set, the crosshead should be put in place and tried in all positions to see that it is true at all points. The top guide can now be put into place and lined down so as to allow the crosshead to work freely.

In lining two bar guides, run a small line through the cylinder. Measure the distance from bottom face of crosshead gib to centre. The bottom guide should be set this distance from line. The crosshead can be calipered and top guides set the required distance from bottom guide.

A gauge must be used on both sides and guides kept central with line and square with top of frame. The crosshead should be put in place and as many liners as possible used under top guide, so that they can be closed as the crosshead wears.

Valves and Steam Chests.—In truing up old valve seats, it is best to use a valve seat-facing machine where one is obtainable. If a machine is not in use it is necessary to chip with chisel and hammer if the seat is bad, then use a bastard file to produce a fine bearing with the face plate or calve. A smooth file or scraper can then be used to bring the surface down to a good bearing. The valve seat must be kept the same height at all points.

To line down the pressure or valve balance plate, get the exact height from the seat for the gasket to the top of the valve, and the thickness of the chest outside of the gaskets. Then allow for the thickness of the gaskets and about 1-32 inch to draw down and the plate to these measurements.

In putting up steam chests and covers in erecting shop, care should be taken to see that the gaskets are well fitted to the grooves in the cylinder. The nuts on the cover must be drawn down very tightly to prevent the steam chest leaking around the joints.

Steam and Dry Pipes.—This is one of the most important parts of the engine and requires some skill in making proper joints between the pipes so that all leaks will be avoided. The joints must be perfect in every respect with as wide face for the flat bearings as possible. If this work is not carefully done, when the engine has made one or two trips in heavy service, more or less of it will have to be gone over again.

In grinding joints, No. 1 emery may be used for all brass to brass joints, and No. 2 emery for all iron to iron joints. The joints should be ground until there is about $\frac{1}{4}$ inch bearing in the worst place.

If joints are badly worn, face them off in machine or scrape before grinding. A tool similar to a carpenter's brace may then be used in grinding.

Use block and tackle where necessary in applying pipes. When dry pipe is put in place, see that a perfect joint is made between ring on pipe and flue sheet. Fasten pipe securely to dry pipe with key bolts and strap, or flange with bolts and nuts. Be sure to keep top level. Fasten to dome and put in throttle box and

RAILWAY MILEAGE AND COST OF CONSTRUCTION

throttle. Connect up throttle rigging carefully and securely so that no trouble can occur in the future.

Blacksmith Shop.—In this department it is usually necessary to do more or less car work, track and bridge work in connection with the regular locomotive repairs. To do this successfully, the foreman should carefully classify the work, giving to the furnaces such parts as can be most successfully done in this way, and distributing among the forges the remainder of the work in such a way as to give to each fire a regular class of repairs.

The bolt heading machinery, shears, and furnaces necessary to heat all bolts should be located in close proximity so that when iron is delivered to the shears it can be cut off, the bolts passed to the furnaces, headed and delivered to storage bins with the least possible handling. Such an arrangement as this in any large shop where thousands of bolts are made each month will save much time and money.

Particular attention must be given to the furnace, which should be oil and not coal, to see that it is capable of heating the iron as fast as

2. Flanging flue sheets and door sheets, rolling side and crown sheets and bolting fire-boxes together ready to rivet.

3. Riveting, chipping and caulking firebox, putting in place, setting mud ring and riveting complete.

4. Putting on crown bars, driving stay bolts, renewing side sheets, front and back flue sheets, flanging and putting on back door sheet and throat sheet, cutting out, rolling, and applying smoke box.

5. Cutting out all rivets, breaking out stay-bolts, and removing mud rings, fireboxes, and other parts.

6. Tapping stay bolt holes, screwing in stay bolts, setting to place, and cutting ready to drive.

7. Cutting out flues, removing from boiler and putting in rattler.

8. Setting flues in boiler complete.

9. Flue plant.

Drive rivets with pneumatic hammer wherever possible. Break out stay bolts with pneumatic ram. Chip and caulk by air and not by hand. Use air motor to tap stay bolt holes and

DRAW BAR SPRING FOLLOWER PLATES

System.

1. Bar iron brought into shop, cut to length, and put into oil furnace.
2. Remove when hot, 2" hole punched through to within 1/4", leaving dowel on opposite side of plate, and plates loaded on iron truck.
3. Deliver to store shed.

Absence of System.

1. Bar iron delivered to shears.
2. Plates cut to length, heat in coal furnace, and 1/8" hole punched.
3. Deliver to smith at forge.
4. Round bar iron 1-1/8" diameter delivered to shears.
5. Cut to 6" lengths.
6. Deliver to upsetting machine.
7. Dowels upset to 2" and cut off.
8. Dowels delivered to blacksmith.
9. Heat in open fire, put in plate and rivet on anvil with sledge.
10. Deliver to store shed.

BRAKE LEVERS

System.

1. Bar iron brought in, levers cut off and put in oil furnace.
2. Heat, draw out under hammer, cut to length, and load on iron truck.
3. Deliver to drill press.

Absence of System.

1. Bar iron delivered to shears.
2. Cut off.
3. Put into coal furnace.
4. Heat and draw out under power hammer.
5. Deliver back to shears.
6. Cut to length.
7. Load on trucks and deliver to drill.

the machine will head the bolts. Oil furnaces and bulldozers or air bending machines should be provided for car work, such as arch bars, brake hangers, brake rods, etc. For making brake staffs, eccentric jaw pins, and all similar work which can be handled in dies, a Bradley cushion hammer or one of similar make should be used. These hammers are not expensive in first cost, but their use will have a very gratifying effect in reducing the cost of repairs.

The above illustration gives some idea of what may be accomplished by a systematic classification of blacksmith work.

Boiler Shop.—Greater gains can be made in this department than in any other, perhaps, by a systematic classification of the work. If no particular attention is given to assigning certain men to certain classes of work, it will soon be found that the output of the plant is being limited on account of slow returns from the boiler shop. The repairs in this department, no matter whether the shop be large or small, may be organized and men regularly assigned to certain operations in the following manner:

1. Ash pans, new and repairs, includes putting upon engine.

screw in stay bolts. Use a small automatic gang drill to drill detective holes in stay bolts. Don't heat them and punch. It destroys the even quality of the iron. Cut out, expand, and roll flues by air. Cut off safe ends with bevel rotary cutter. This cuts and scarfs the piece all in one operation.

W. S. COZAD,

Shop Specialist, Erie Railroad Co.

Railway Mileage and Cost of Construction. The following table, which has been compiled both from the special report of the Bureau of Statistics of the United States Department of Labor and from other authorities, attempts to present a picture of the condition of railroad transportation shortly after the beginning of the 20th century. While it has been possible to obtain a reasonably accurate estimate of the number of miles of railway in each country, the lack of census figures in several cases has prevented the completion of the column relating to population, while the absence of any authentic information concerning the financial standing of the roads has necessitated the omission of the

RAILWAY PASSENGER STATIONS OF THE WORLD

cost of construction, or capital cost, in many countries. The statement follows:

| Country. | Year. | Mileage. | | Cost of Construction. | |
|-------------------------|-------|----------|-----------------|------------------------|---------------------------|
| | | Total. | Per 10,000 pop. | Total capital or cost. | Capital or cost per mile. |
| 1,000 of dollars. | | | | | |

Railway Passenger Stations of the World.

While there are resemblances between the facilities provided for railway passenger traffic in large cities and at important railway centres in various parts of the world, there are also distinct differences, due to the varying conditions and to the diverse general methods in vogue in the United States and foreign countries.

Generally speaking, large passenger stations may be classified into the following types:

First.—Terminal stations at or near the level of the adjacent streets, such as the existing Grand Central Station, New York; the Union Station, Saint Louis; the North and South Union Stations, Boston, Mass.; the Liverpool Street, Euston; Great Central, Victoria, etc., London, and Frankfurt, Germany.

Second.—Terminal stations elevated above or partly above the streets, such as the Jersey City Station of the Pennsylvania Railroad, Jersey City, N. J.; Broad Street Station, Philadelphia; Waterloo and Saint Pancras, London; Saint Lazare, Paris; and the Central Station, Antwerp.

Third.—“Through” stations at street level, such as the Indianapolis Union Station and the Omaha and Saint Paul stations in the United States, and the Hanover Station, Germany.

Fourth.—Terminal and “through” stations combined. (a) at street level; (b) above it; (c) below it; and (d) partly above and partly below street level, such as (a) Buffalo, N. Y.; (b) Cologne, Germany; (c) proposed Pennsylvania Railroad Station, New York, and Waverly, Edinburgh; and (d) New Union Terminal, Washington, D. C., Queens Street, Glasgow, Scotland, and Dresden, Germany.

Table I. shows certain features related to operation, and is made up from a recent (1903) investigation of six large passenger stations of the United States, representative of the best practice.

SPECIAL INFORMATION RELATING TO SIX (6) LARGE UNITED STATES PASSENGER STATIONS.

There are certain features that do not appear in this table. For example, in Paris it is the custom of the people to go out of the city in large numbers on Saturday and Sunday, especially in the summer time, and, to accommodate this immense crowd, the cars of the Western Railroad running out of the Saint Lazare Station are double-decked. On these days, the facilities of this station are taxed to their utmost and far

beyond the ordinary suburban business, which is always very great, particularly since the line was built crossing the Seine to the Champ de Mars.

To facilitate the rapid handling of traffic in the station, the train arriving with its load of passengers is not hauled out to allow the locomotive to pass out, but it remains on the arriving track while it is uncoupled and moved and turned by a combined traverse and turntable, and passes out of the station on an adjacent service track to the water-tank and coal-shutes, and then backs down to its train, couples on, and is ready to haul it out, head on, as soon as it is loaded. The side doors of the cars facilitate unloading and loading, so that the train is ready to be pulled out loaded by the time the engine is coupled on. This plan saves time, saves movements of trains and permits the locomotive to travel head-on whether coming in or going out.

This same plan of car doors in Great Britain facilitates egress and ingress. The writer timed the egress of 500 passengers from an arriving train at the Caledonian Railway Station, Glasgow, and recorded *ten seconds* as the time to wholly empty the train from the instant it stopped at the platform. The Illinois Central World's Fair trains in Chicago in 1893 adopted the same plan with great success in the prompt handling of large crowds. In London there is also an immense traffic on certain days, such as Bank Holiday, when all station facilities are taxed to their utmost.

There are other movements, also, to be taken into consideration in estimating the vast amount of work done at important railway stations. Empty trains called "drafts" or "carriage" trains must be hauled in from the storage yards, and hauled out empty to them. The locomotive which brings in the train must pass out to the round house. To give an idea of these extra movements, the following is quoted from the latest time tables of the South Union Station, Boston, Mass., and the Grand Central, New York:

SOUTH UNION STATION, BOSTON, MASS.

RAILWAY PASSENGER STATIONS

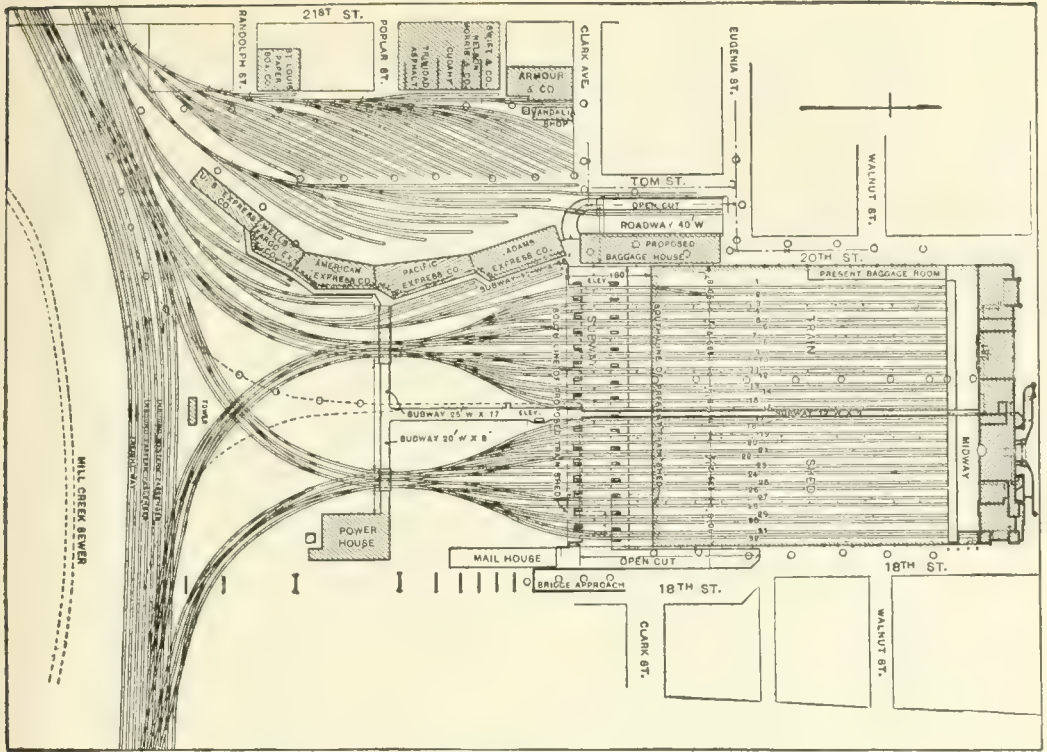

PLATE I.—Approach Tracks to Union Station, Saint Louis.

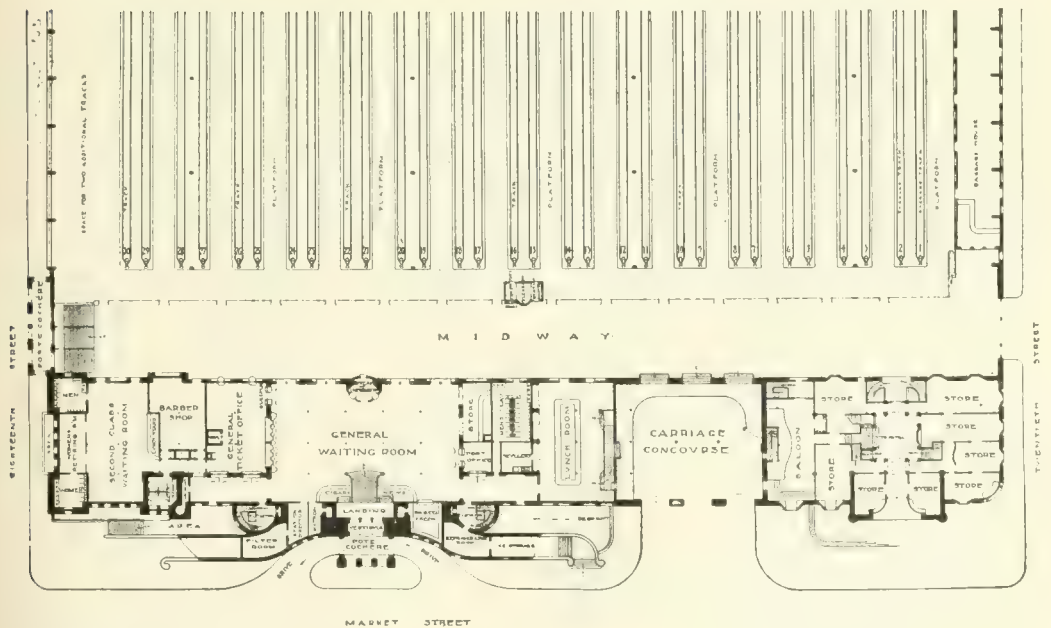

PLATE II.—Ground Floor: Midway and Tracks, Saint Louis.

RAILWAY PASSENGER STATIONS

As 88 regular scheduled trains arrive and depart during the busiest hour—5 to 6 P.M.—at the South Union Station, Boston, the number of movements required to accomplish this regular train work is very great, and the signal and interlocking mechanisms must necessarily be of the most approved kind.

It is quite common, however, to find a great number of regular train movements in stations that do not rank in size with the two above mentioned. In 1901 the Union Station, Saint Paul, Minn., was handling 202 regular trains on ten station tracks, of which 92 per cent had to be handled on six tracks, which required, between 8 and 9 A.M., 96 train movements, and all this was done with hand switches. This station is used jointly by ten important western railroads, and is a very busy station. One million pieces of baggage were handled in 1901—a daily average of 2,216. The average at the Grand Central Station, New York, in the same year was 2,654 pieces.

It is interesting to know something of the character of the approaches to large passenger stations over which so many trains pass daily,

and especially during the busiest hour. The information can best be given in a table where the work to be done and the facilities in the way of approaches are placed side by side.

The foregoing table is indicative of the traffic over approach tracks, but one should know the methods of handling it. All of the approach tracks may not be available for the traffic, and the ratio of station tracks to approach tracks, and of trains, as they appear in the table, may be very misleading, if we expect to learn from it just how many movements there are in the busiest hour over each track. One or more tracks may, for good reasons, be at that time comparatively idle, while another may be hot with wheels passing over it. The writer is enabled to show the actual number of movements over one of the approach tracks at the Grand Central Station, New York, on 21 March 1904. There are four approach tracks, and by the station time card there are in the busiest hour 34 arrivals and departures, or 8.5 trains per track in that hour, as per the above table.

There are 18 tracks in the station. This is at 45th Street. At 49th Street these tracks converge into four tracks, to enter the approach to the tunnel. They are numbered from east to west. Nos. 1 and 2 are south bound (toward the station) to 54th Street. (This road runs left-handed from a point some miles out into the station.) From 54th Street, south, for a distance of about 1,600 feet all south bound traffic is confined to track No. 2—No. 1 being used as a north bound track for shop trains and engines crossing over to tracks 3 and 4 at 54th Street.

This crossing point is the busiest piece of track on the approach, and for the hour between 8 and 9 A.M. there are 25 scheduled trains and 5 light engines south bound, and 8 trains and engines north bound, passing over this stretch of track—38 distinct movements in one hour, or one in every 1.6 minutes. This is not an exceptional performance, but daily practice. The information is given for the encouragement of any railway companies which contemplate a busy traffic over a small number of tracks.

It is possible in the space allowed to briefly give only the specially interesting features of one or two of each of the four classes, or types, referred to at the beginning of this article.

As illustrating the first type, namely, terminal stations at street level, the Union Station, Saint Louis, and the Frankfort Station, Germany, have been selected.

The second type, namely, terminal stations elevated or partly elevated above street level, is illustrated by the Reading Terminal, Philadelphia, and the Saint Lazare, Paris.

The third type, namely, through stations at street level, is represented by the Indianapolis Union Station.

The fourth type, namely, terminal and through stations combined, partly elevated or depressed, the Union Terminal, Washington, D. C., now under construction (April 1904), and the Dresden Station.

The Saint Louis Station is one of the largest in the world, for it has more tracks than any—30, with space for two more in the train shed, though not so many trains arrive and depart as with some other stations. Its traffic, however, is very important, as it is the terminus

TABLE SHOWING APPROACH TRACKS AND TRAFFIC ON THEM.

| STATION | No. of approach tracks | No. tracks in station | Trains in 24 hrs. | Trains in 1 hr. maximum | Ratio between sta. tracks and approach tracks | Remarks |

GRAND HALL, UNION STATION, ST. LOUIS.

RAILWAY PASSENGER STATIONS

of 22 trunk lines and the trains are mostly through trains—very long and heavy. The trains approach from two directions, from the east over the two bridges that span the Mississippi River, and from the west by trunk lines from that direction. The original lay-out of the approach tracks had serious objections and radical changes are now being made to improve the entrance to the station.

Plate I. shows the new approach tracks, increasing the number from four to six. It will be seen that these approach tracks spread out into really four groups upon entering the immense train shed. The plan of the ground floor of the station, with the "Midway"—concourse—and the station end of the track, is shown on Plate II. A good idea of the interior may be had from Plate III.—showing "The Grand Hall." The station is owned by "The Terminal Railroad Association of Saint Louis." The roads using it form the proprietary company. The total first cost was \$6,500,000—the real estate costing \$4,500,000, and the buildings, etc., \$2,000,000. The cost of operation during the year 1898 was:

| | |
|--|--------------|
| Rental | \$327,507.40 |
| Less revenue from privileges..... | 103,526.51 |
| Net rental | \$223,980.89 |
| Actual operating expenses and maintenance..... | 290,636.44 |
| Total annual cost..... | \$520,617.33 |

The average charge per car for that year was \$1.58. The cost is apportioned among the roads using the station on a "wheelage" basis. This word must not be understood to mean wheels. It means cars (coaches), and the charge is on the basis of "equalized cars," as explained below. The following paragraph from the agreement between the Association and the various railways occupying the station will show clearly the method of apportioning the cost:

An accurate record shall be kept by the Terminal Company of all passenger, baggage, mail, express, sleeping, dining and special cars, in and out of the said Union Station during each calendar month, and said Railway Company shall pay said Terminal Company such proportion of said balance, as the number of such cars of said Railway Company in and out of the said Station, bears to the whole number of such cars in and out of lines using said Station facilities during the month; and in so ascertaining the number of such cars in and out, cars hauled in trains, the runs of which terminate within 37 miles of said Union Station, shall be counted as one-third part of a car, in all other cases as one car.

Frankfort-on-the-Main, Germany.—This station is owned by the Prussian government and the Hessian Ludwigs Railroad. It is really a street level station, the entire area in front and on the sides having been raised and embellished with grass plots, parks, and ample approach area. The general railroad approach differs from that at Saint Louis, as groups of tracks come into it direct. In order to prevent grade (level) crossings, the tracks approaching from different directions are at different levels for some little distance from the station, those coming in from lateral directions passing over those entering directly. The train shed is very large, but not equal to that of Saint Louis, being 551 feet by 610 feet with an area of 336,110 square feet, while the Saint Louis train shed is 606 feet by 700 feet, with an area of 424,200 square feet, and there are 18

tracks in the train shed at Frankfort. Plate IV. is a photographic view of the front of the station, and the train shed is seen in Plate V. The latter shows clearly the three great steel arches and the very substantial and permanent character of the wide platforms. The platforms of all large German stations are generally much more solid and are much wider than is often found in the United States.

The Reading Terminal, Philadelphia, is a characteristic station of the second type, elevated above the street. The train shed is one single metallic arch, three-pointed, hinged at the crown and covering the entire width of the tracks and platform, the width at springing line being 260 feet. The height is 88 feet, the length 502 feet. The total length of the station, including the head house, is 663 feet. The 13 tracks starting in the train shed reduce to 5, 350 feet from it. About 1,650 feet from it, they separate into two lines of two tracks each. The terminal yard is reached over an elevated structure, the plate girders bridging the street, or viaduct, on columns. This structure is half a mile long. The elevation of the rails is about 25 feet above the street level.

The station proper is in the second story of the head house—the ground floor being used for entrance, waiting rooms, ticket offices, baggage rooms, etc. The general and administrative offices are above the second story. The ground floor under the train shed is used for a large market, cold storage, and a refrigerating plant. The operating plant of the station is also here. The main waiting room on the second floor is very lofty, occupying two stories in height. There are also on this floor the dining, lunch and smoking rooms.

There are two large passenger elevators and a broad stairway. Each baggage room has two elevators (lifts) for baggage trucks to the train-shed floor. There are four more stories for offices. The floor of the elevated train shed is constructed of buckled plates carried by plate girders. There is a layer of cement over the plates and then one inch of Neuchâtel asphaltum. The cross-ties are laid in asphalt concrete, the platforms being made of the same material. The surface of the platforms is eight inches above the rails. Large frames of heavy hammered glass are built into the platforms to help in lighting the spaces underneath.

The building is a monumental structure, Italian renaissance in style, the exterior faces on the streets being of pink granite to the first story, and above that pink brick and cream terra cotta.

Some items of cost may be of interest. The head house cost \$36 per square foot of superficial area, or 23.1 cents per cubic foot of contents. This cost is for construction alone, and does not include heating, lighting, elevators, water supply, etc. The train shed, including foundations and apartments underneath, cost \$8.53 per square foot of surface covered. Plates VI. and VIa show respectively the ground floor, and section of train shed and foundations.

The Saint Lazare Station of the Western Railway, Paris, is an example of a terminal station, partly elevated and partly at street level. In front of the station the rue Saint Lazare is considerably below the level of the tracks, but on the eastern side the station tracks are at the level

RAILWAY PASSENGER STATIONS

of rue d'Amsterdam. The ground still rises and the rue de Londres is considerable above the level of the approach tracks and a little further on, at the rue Saint Petersburg, it requires a car lift of about 31 feet to raise the express freight from the track level to the street. There are 31 tracks in the station—27 for passenger trains and 4 for locomotives and other station service. About a quarter of a mile from the station, the tracks converge into six entrance tracks and pass through a tunnel about 1,000 feet long, and then through a deep cut. Three quarters of a

In front of the station and connected with it by a covered elevated gallery, is the Hotel Terminus, owned by the railway company. In the interior of the station, reached by several broad and easy stairways, is the Grand Hall "Pas Perdue," 630 feet long and 72 feet wide, from which exits lead to the waiting rooms and offices, etc., which are between this hall and the concourse. The baggage after being raised and registered, is raised to the track level on small trucks by means of movable inclined lifts hauled up by endless chains worked by hydraulic power.

PLATE VI.—Ground Floor, Reading Terminal, Philadelphia.

mile from the station, the tracks diverge—two to the west and four to the west of north. Near the point where the lines separate, there is a very large terminal yard. This is one of the best equipped stations in the world. All parts of it, passenger and freight stations, shops, round houses and yards are fully supplied with hydraulic and electric power and light. It has 1,200 daily arrivals and departures of trains. Few exceed it in volume of traffic. It covers 27 acres. Of the various signal towers one commands the three groups of entrance tracks.

(See Plate VIII.) The traverse turntable is shown on Plate IX.

The *Indianapolis Union Station* is a typical station of the third type, "through" at street level. Five proprietary railway companies united (in 1888) their properties and organized this company. Nine other railways were admitted later as tenants with equal privileges to the five, all having a joint use of the station as well as of a belt line railway. The main building is an imposing and commodious structure, devoted almost exclusively to Union Station purposes.

1. Front View of Station, Frankfurt, Germany.

2. Train Shed of Frankfurt Station.

RAILWAY PASSENGER STATIONS

Adjoining and extending past the head house in each direction, and open at both ends for through tracks, is a train shed 740 feet long and 200 feet wide, with nine passenger and two freight tracks. The entire station cost about \$1,000,000. The operating expenses per annum averaged in 10 years—1889-1898—\$60,000 or 23.7 cents per car. The annual fixed charges were about \$52,000, or 20.49 cents per car, to which should be added \$11,500 for track expenses, or 11.06 cents per car, making a total of about \$123,500, or 55.5 cents per car.

with hydraulic and electric power and appliances. The cost of the station with freight depots and other appurtenances, was \$5,315,000.

The Union Terminal, Washington, D. C., now under construction (April, 1904) is a good example of a terminal and through station combined—the fourth type. It is partly at street level and partly below the same. The six railroads, four from the south and two from the north, have thus far handled their passenger traffic at two stations at a considerable distance from each other, one near Pennsylvania Ave-

TWELFTH STREET

PLATE VIa.—Market House, Reading Terminal, Philadelphia.

The North Station, Hanover, Germany, is an excellent example of a continental through station at street level. Hanover is an important city of Central Germany on through lines from Frankfort to Hamburg and Bremen, and from Cologne to Berlin. Four important roads occupy the station. The general plan comprises a commodious head house 566 feet long and 92 feet wide, and, back of it and attached to it, a train shed of about the same length, 289 feet wide, with nine tracks. The station is furnished

with hydraulic and electric power and appliances. The cost of the station with freight depots and other appurtenances, was \$5,315,000.

The new station is to be near the Capitol. The Philadelphia, Wilmington and Baltimore Railroad reaches it by a connection with its main line entering Washington, and leaves it from the low level by means of a double track tunnel passing under Capitol Hill near the Library of Congress, by which the roads from the south will reach the station. There are 11 through tracks at the low level and 18 terminal stub tracks at street level—five of those above and

RAILWAY PASSENGER STATIONS

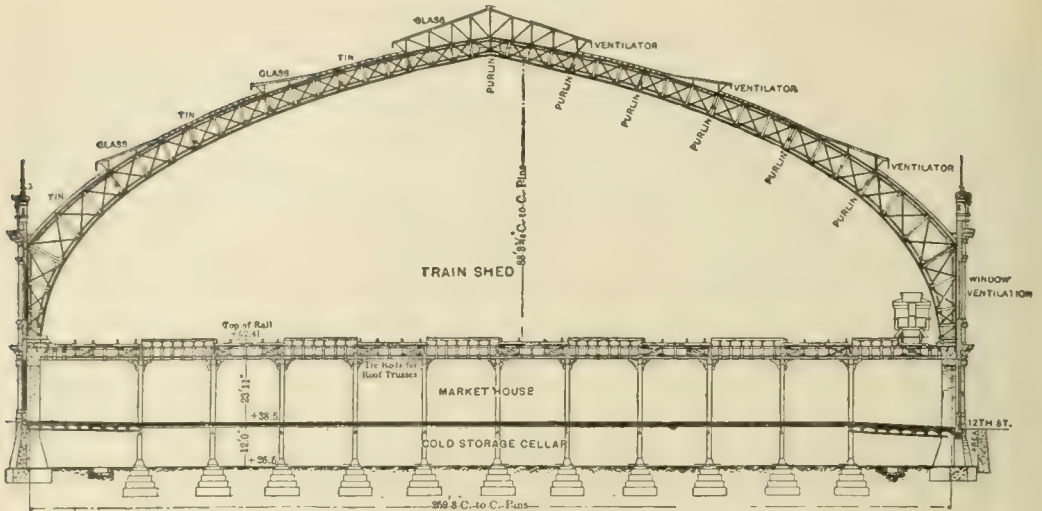

PLATE VII.— Cross Section of Train Shed Looking South, Reading Terminal, Philadelphia.

the same number below will be used for baggage tracks. Without going into details, certain interesting features should be referred to. (See Plate X.)

The general government participates in the station by contributing about \$4,600,000 toward the elimination of grade (level) crossings and towards the new plaza. It is estimated that the cost of the entire improvement will be about \$14,000,000.

The station building proper is about 620 feet long, to be built in white marble and granite. The three entrance arches are 50 feet high, lead-

ing into a vaulted open air vestibule. The arches at the end are for carriages, one arch being for the use of government officials, and leading to a suite of apartments for the exclusive use of the President of the United States and the guests of the nation.

Attention is called to the very large size of some of the rooms. The general waiting room is 128 feet by 236 feet and 90 feet high, covered by a Roman barrel-vaulted roof. The concourse is also of extraordinary dimensions, 80 feet by 745 feet, the whole width on both sides of the separating fence being 130 feet. The

PLATE VIII.— Inclined Baggage Carrier, Saint Lazare, Paris.

INTERIOR VIEWS OF STATION, DRESDEN, SAXONY.

RAILWAY PASSENGER STATIONS

platforms are covered by umbrella sheds, adapted to the mild climate of Washington. The platforms average 900 feet long and 21 feet wide, made of concrete laid in cinders, and faced with one inch of cement. Plate XI. shows the umbrella sheds.

The baggage is handled in the basement, reached by two driveways. There are four baggage subways, two longitudinal, 16 feet wide, the whole length of the building, and one transverse 60 feet wide at the station end, and one at the outer end of the platforms 20 feet to 42 feet wide. H Street, 80 feet wide, is carried under the station, and K Street, also, outside of the station.

Other interesting provisions are an invalid's room, offices of a resident physician, several mortuary chambers, dressing-rooms with bath, a Turkish bath and swimming pool. The northern approach is on a masonry viaduct crossing over all streets. There are eight tracks upon it.

The Waverley Station, Edinburgh, Scotland, is another interesting example of the fourth type, being wholly depressed, and partly through

of tasteful ornamentation within and without. It has all the numerous and special conveniences of the most modern United States stations, and one feature not often found in this country, and that is abundant station service—porters, waiters, etc., in which European stations are generally far in advance of stations in the United States. The station is everywhere brilliantly lighted by electricity and is always a model of cleanliness. There are two waiting-rooms for first and second-class passengers, and two for third and fourth, with several restaurants. There is a police station, branch post-office, telegraph, telephones, a physician always in attendance, with the usual other facilities. (See Plate XII.)

The foregoing descriptions and illustrations, and the tables and plates, are sufficient to give an idea of the facilities in the United States and in some other countries where large numbers of passengers are handled. The increase of passenger traffic in many large stations has compelled enlargement of facilities. Old stations, which a few years ago were considered ample, are now under reconstruction to avoid either the

PLATE IX.— Combined Traverse Turntable, Saint Lazare, Paris.

and partly terminal. The cost of its construction, including property, was \$7,500,000. It was recently completed. The cost of operating it is about \$165,000 per annum. It has a large passenger traffic—630 daily arrivals and departures of trains and 40 in the busiest hour. There are four approach tracks on each end and both in tunnels. Through trains can pass through the station on each side on two through tracks, and there are 8 platform terminal tracks on the south end, and 7 on the north end. In general physical features the approaches and the station area are somewhat similar to those of the proposed Pennsylvania Railroad station in New York, reaching it from under the Hudson River and the East River.

The Dresden Station, Germany, is another European station of the fourth type worth noting. It has six terminal tracks at street level and eight through tracks above. This station, for architecture and for general convenience, cannot be surpassed. The materials of construction are stone, iron and glass with a profusion

of tasteful ornamentation within and without. It has all the numerous and special conveniences of the most modern United States stations, and one feature not often found in this country, and that is abundant station service—porters, waiters, etc., in which European stations are generally far in advance of stations in the United States.

In Chicago the Lake Shore and Michigan Southern Railroad and the Rock Island and Pacific Railroad have recently entirely rebuilt their joint station, raising their tracks 15 feet above the street level.

In Great Britain the large Caledonian Railway station in Glasgow, the principal terminal of that road in that city, is being greatly enlarged and improved.

Waterloo Station, London, one of the largest in the world, and with an immense traffic, has been found to be inadequate for its business and is being wholly rebuilt on an entirely different plan from the old station, which in the course of years had grown by additions which had destroyed entirely the unity of the original design.

In Paris in 1900 it was found necessary to bring the Orleans Railway farther into the city, and an approach several miles in length was built along the bank of the Seine below the

RAILWAY PASSENGER STATIONS

PLATE X.—Plan at Street Level. Union Terminal, Washington, D. C.

PERSPECTIVE VIEWS OF THE NEW UNION TERMINAL, WASHINGTON, D. C.

RAILWAY PASSENGER STATIONS

street level to the Quai d'Orsay in the Exposition grounds, opposite the end of the Alexander III. bridge. The approach and the station tracks are entirely below the surface.

The new Gare de Lyons, the great terminal station in Paris of the Paris, Lyons and Mediterranean Railway, is approaching completion and on a scale far beyond that of the former station; in fact, the old station is entirely done away with.

One of the most important terminal works now under way in the world is the reconstruction of the Grand Central Station, New York. This station has had successive enlargements from time to time in the past to endeavor to meet the steadily increasing traffic, and it was only three years ago that very extensive interior changes were made in the station, throwing

the three waiting rooms which previously existed, into one large commodious and elegant room, concourse, etc., but the traffic has already outgrown these facilities. The company wisely decided to adequately prepare for its business, but, as to do this no ordinary modifications would meet the requirements, it was determined to raze the present station to the ground and build a new one, and while doing this to make certain other radical changes to meet new conditions and connections. The plans of the station and other facilities are not sufficiently advanced for description at the present time.

Civil Engineer, New York.

Railway Postal Cars, Steel. The all-steel postal car was first used by the Erie Railroad. The first of the type was built by the Standard Steel Car Company of Butler, Pa., and included in the exhibit of railway appliances incident to the International Railway Congress at Washington, 4-13 May 1905. It was also exhibited at Buffalo on 31 May 1905, at Cleveland on 2 June, and at Cincinnati on 5 June. The final exhibition was at Chicago on 7 June 1905, the car going into regular service that date on the Erie mail route between Chicago and New York.

which is a 5-inch air space. Then is a layer of steel flooring which is covered with a cork and cement composition $\frac{3}{4}$ -inch thick, and over this a thin maple wooden floor runs lengthwise with the car. In designing the car particular attention was paid to strengthening its ends, thereby obtaining the utmost resistance in case of collision.

The end sills are of pressed steel in channel form $\frac{3}{8}$ -inch thick, covered by $\frac{1}{2}$ -inch steel plates 12 $\frac{1}{4}$ -inches wide to which the steel flooring is riveted. The end plate at the top of the car is of $\frac{1}{4}$ -inch steel, 10 inches wide, in 'L' shape with a 4-inch flange. The end uprights consist of two door posts, two end posts and two intermediates. All are made of angle iron securely riveted to the floor and roof. The end construction is therefore of extraordinary strength.

It was anticipated that the car would move noisily and be more difficult to heat in winter than the ordinary car, but these disadvantages have been largely overcome by the triple floors, the double lining, and the air space. The interior furniture conforms to that of the ordinary standard postal car, but all the woodwork has been covered with fireproofing. The steam heat is provided by the direct system, and there is also a Baker heater for emergency use.

The car is 65 feet long and weighs 114,440 pounds, less than 15 per cent. more than the 65 foot wooden postal car which weighs 101,700 pounds. The steel underframe is designed so that the weight principally rests on two center sills. These sills are 16 inches apart and are made of $\frac{3}{8}$ -inch steel plate, built up as a wedge shaped box girder, with a maximum depth of 22 inches in the center of the car and a minimum depth of 13 inches at each end. The framework of the body of the car is made of $\frac{1}{8}$ -inch steel plates, the roof of $\frac{1}{8}$ -inch steel plates, all riveted together as in boiler construction; the door and window frames being reinforced by heavy steel plating. The interior of car is lined on the sides, roofs, and ends with composition board $\frac{3}{8}$ -inches thick, with a $\frac{3}{4}$ -inch layer of hair felt against the steel sides and 2-inch air space between hair felt and composition board. The floor of the car is of $\frac{1}{8}$ -inch steel plates securely riveted and built up as follows: At the bottom a wooden deafening floor $\frac{3}{4}$ inch thick is covered with a layer of hair felt above

Nineteen acetylene gas lights from a plant furnished by the Commercial Acetylene Company aggregate a total of 712 candle power, in contrast with the 400 candle power of the ordinary postal car.

The steel postal car was the conception of Mr. F. D. Underwood, President of the Erie Railroad, and was adopted on that line to add to the safety of the United States mail agents and postal clerks whose runs are over the Erie Railroad. The steel car has, beyond question, a resistance so much greater than that of the wooden car that the danger of telescoping is practically eliminated, no matter how great the shock. The danger of fire is also eliminated in the case of the steel car, the interior being nearly and the exterior quite fireproof. Even under the most strenuous conditions of operation, an impact sufficient to buckle or crumple the steel postal car is almost beyond imagination. Even if a steel car were to buckle because of the great resistance, the crumpling would be slow and free from splinters and fire. The occupants

RAILWAY RECEIVERSHIPS

could hardly be seriously injured, at least not from the causes which, in the wooden cars, are their greatest danger,—splinters, fire, and scalding steam from the locomotive.

That the steel postal car adds largely to the safety of the postal clerks, was thoroughly demonstrated in the accident to the Erie Railroad train No. 8, one mile west of Burbank, Ohio, on 23 July 1906. This steel postal car, number 699, was next the engine and the train was running about 45 miles an hour when the derailment occurred. The car rolled down a 20-foot embankment and turned over on its side, stopping about 30 feet from the track. No one of the three occupants was seriously injured, and the car received the roughest usage with practically no damage.

C. S. SIMS,

Assistant to President, Erie Railroad.

Railway Receiverships and Reorganizations. It would scarcely be expected that an industrial institution of such magnitude as the American railway system could develop within the comparatively short period since the year 1830 without some evidences of friction. The promoters of railway enterprises have not always thoroughly understood the conditions of the industry nor the commercial needs and possibilities of the regions served by their lines; investors in railway securities have sometimes been too greedy of large and immediate gains and too reluctant to lay, through abstinence from immediate returns, a solid foundation for future prosperity; legislatures have too frequently and too quickly passed from the extreme of unduly fostering railway construction to that of drastic anti-railway enactments. In consequence of these and many other misconceptions and mistakes many railway corporations have, at different periods in their history, been unable to provide during times of extreme business activity and prosperity for the regular recurrence of industrial depression. Earnings during good times have been wholly distributed among security-holders and no surplus accumulated for the period of relatively bad times certain to follow. Even the normal depreciation of the property has, in some instances, been underestimated or even utterly neglected, renewals and repairs have not been made or if made they have been charged to capital and not

to expenses, where they belong. Such practices, supplemented in their evil consequences, by a good deal of positively vicious restrictive legislation, could lead to but one result, and that the bankruptcy of the corporations chiefly suffering from them. Indeed a study of the rapid changes in traffic conditions during successive years shows that even the wisest management might well have been perplexed as to how best to prepare for the exceedingly uncertain future. The statement at the foot of preceding column shows the aggregate transportation performed by the railways of the United States during each fiscal year from 1889 to 1902 inclusive, as measured in passenger miles and freight ton-miles.

It must be perfectly obvious that unless such heavy decreases in traffic as occurred after 1893 could be offset by advances in charges sufficient to prevent corresponding decreases in revenue and if they had not been forestalled by the accumulation of a surplus during more prosperous times, the consequences must involve reductions in the payments to security holders. This is precisely what occurred and in the case of those companies whose earnings during the more prosperous period had barely sufficed to meet interest charges, leaving nothing for dividends to stockholders, the reduced ability to pay interest on bonds frequently led to insolvency and the appointment of receivers. It should be observed, in passing, that in spite of the 15 per cent reduction in the volume of passenger traffic between 1894 and 1895 the average revenue per passenger per mile increased barely one half of one mill and that while the volume of freight traffic decreased over 14 per cent between 1893 and 1894 there was an actual decrease in the average receipts per ton per mile. Although the volume of freight business done in 1893 was not again equaled until 1898, each successive year from 1893 to 1899 shows a reduction in the average ton-mile receipts, the aggregate decrease being 1.54 mills, equal, on the basis of the business of 1893, to \$144,125,692. The following table, showing the par value of the railway stocks and bonds, which received no return in dividends or interest, during the years named, indicates the exceeding vulnerability of railway corporations in the face of decreasing traffic and revenue:

| YEAR | Passenger miles | | Ton-miles | |
|----------|-----------------|---------------------------|-----------------|---------------------------|
| | Number | Per cent of previous year | Number | Per cent of previous year |

* Exclusive of equipment trust obligations.

When railway companies are unable to pay the interest on mortgage bonds it is the practice for the trustees under the mortgage, or

RAILWAY RECEIVERSHIPS

other parties in interest, to apply to a court of competent jurisdiction for a receiver to manage the property in the interest of the bondholders. Such receiverships are not always unfriendly to the management in whose charge the corporation became insolvent. Indeed "friendly" receiverships instituted for the purpose of perpetuating the existing management and its policies in spite of its inability to pay interest, and to relieve the property of the burden of such payments in order that it need not be suffered unduly to deteriorate on account of the impossibility of meeting both interest and the cost of ordinary repairs and replacements out of revenue, have been frequent. So liberal has been the policy of some courts in this respect that the device of operation through receivers has even been found a convenient means of providing for the rehabilitation of properties that have been permitted to run down in order to keep up interest and, in some cases, dividend payments. The utility of this device is enhanced by the privilege, frequently allowed, of raising funds for repairs and even for necessary improvements by issuing "receiver's certificates," which are obligations having priority over everything except wages. The extent of the American railway mileage in the control of receivers has at times been appalling, but it is now very much reduced.

The preceding table shows the total railway mileage of the country, and the number of railways with their mileage, in the hands of receivers on 30 June of each year from 1894 to 1902, inclusive.

Nothing could be more significant of the increased prosperity of the American railway system, which has accompanied the general revival of business that has followed the depression of 1893-6, than the decrease shown by the foregoing, in the proportion of the railroad mileage of the country controlled by receivers from nearly one quarter of the whole in 1894 to less than three quarters of one per cent eight years thereafter. The release of railway property from the control of receivers is commonly accompanied by a "reorganization" or readjustment of its capitalization, and this may be secured with or without foreclosure. When reorganization is accomplished without a foreclosure of any of the mortgages standing against the property, it is by agreement among the owners of its various grades of securities. For the purpose of effecting a reorganization it is the practice to appoint committees representing the holders of the bonds or of the stocks and, if it is thought practicable to permit the latter to participate in the reorganization. These committees devise reorganization plans which usually involve the surrender of some or all of the old securities and the acceptance in exchange of new securities bearing lower rates of interest or having a less absolute claim to regular returns or occasionally, of a lower aggregate par value. In several reorganizations the stockholders have been compelled to meet assessments on penalty of forfeiture of interest and in a few cases even owners of bonds have been assessed. When the holders of all grades of securities can be permitted to share in the reorganization and divergent interests can be reconciled so as to obtain an agreement, a foreclosure is unnecessary. It has frequently hap-

| YEAR | Total mileage in the United States | In the control of receivers | | |

pened, however, that the lower grades of securities have had to be excluded from participation, and in these cases their rights must be "foreclosed" by appropriate legal proceedings culminating in sale "under the hammer." The statement on preceding page (compiled by the 'Railway Age') shows, for each of the years from 1876 to 1903, inclusive, the number of railway corporations for which receivers were appointed, with their mileage and the aggregate par value of their stocks and bonds. Similar data are also given concerning the railways sold at foreclosure sales.

While it is not probable that railway corporations will hereafter escape entirely from the misfortunes and mistakes which result inevitably in insolvency, it is gratifying to note evidences of greater wisdom in financial management and to record the impression which appears wholly justified by the facts, that the record of insolvency shown for the worst years of the last great depression will never again be equaled in the railroad field.

H. T. NEWCOMB,

Author of 'Railway Economics.'

Railway Rolling Stock. Between the earliest days in the history of railways when everything was in the most primitive condition, and the immense developments of traffic of recent years, there has been a steady progress while railroad students have applied themselves to the solution of the problem how the increasing traffic could be handled most expeditiously and at the same time economically. One of the most potent suggestions toward the reduction of working expenses is that the rolling stock shall have greater capacity in order to reduce the proportion of dead weight carried. As a result of this, rails have to be made heavier, roadbed more durable, and everything entering into railroad construction more costly. A freight carload not long since was 12 tons, while maximum carloads now reach, for certain commodities, such as coal, 60 to 100 tons, and from 40 to 60 tons for ordinary commercial freight. Locomotives have increased in weight from 50,000 pounds to 300,000 to 400,000 pounds, and the limit is not yet reached. We are taking up rails weighing 50 to 60 pounds to the yard and are putting down rails ranging from 80 to 100 pounds. We are getting away from bridges which were built to endure a live maximum load of 3,500 pounds per lineal foot, and are building bridges designed for live loads of 7,000 pounds and more per lineal foot, and as a consequence, couplings and drawbars have to be stronger and heavier.

Railroads are consuming constantly increasing tonnages of iron and steel in proportion to their mileage, and this tendency will surely continue until the highest factor of efficiency and consequently the lowest possible ton-mile cost of haulage is reached. It is not merely a matter of replacing rails and bridges, locomotives, and cars with heavier ones when the old ones are worn out, but it is more frequently a case of discarding the old for the new before the old equipment has seen half the years of its intended service. Freight cars cannot be made much longer or wider than the present maximum as long as existing curves have to be negotiated, but they may be made higher, be-

cause the almost universal use of the air brake no longer makes it necessary to allow for the brakeman between the car roof and the overhead bridge or viaduct. Their carrying capacity is also being augmented by the substitution of steel for wood.

Changing railroad conditions make it difficult to estimate the life of locomotives, and of passenger and freight cars. There are many passenger coaches in use to-day which were built 30 or more years ago and are still in good condition, if not modern in appearance. The cars that were lightly built 25 years ago have no business in modern heavy trains. On short branch roads they serve their purpose. The custom now is to build with steel underframing like the Pullmans, so that it is almost impossible to injure them in a wreck.

The box car's life is shortest of all rolling stock, and this is owing largely to the changes in construction. The capacity of cars has increased from 40,000 to 80,000 or 100,000 pounds each, and usage is rougher. The use of the air brake has helped to preserve them, but it is hard service at the best in the present-day long, heavy trains. There are many box cars running, however, which have seen more than 25 years of service, and their life might be averaged at 20 years. There is no reason why the steel gondolas should not last 30 years or more, as there is less likelihood of their wearing out. When a box, freight, or passenger car serves its time, there is little to be scrapped. The trucks and rods are taken out and the wooden portion is burned or used for some purpose, such as toolhouses along the line.

Car equipment is not always discarded because worn out, but it may be out of style, or of too small capacity. One of the results constantly sought by railroad management is the reduction of hauling expense per ton per mile, and no road at this time thinks of a box car of less capacity than 60,000 pounds, and 80,000 or 100,000 is preferred. Monster locomotives and long trains of mammoth cars carry an immensely larger quantity of freight over the road in less time than formerly.

At a recent inventory it was found that there were in the service of the railways in the United States 44,871 locomotives classified as follows: Passenger, 10,870; freight, 25,944; switching, 8,057. The total number of cars of all classes was 1,803,389, assigned as follows: To the passenger service, 48,140 cars; to the freight service, 1,693,782 cars, the remaining 61,467 cars being those employed directly by the railways in their own service. Cars used by the railways that were owned by private companies and firms are not included in this statement. The average number of locomotives per 1,000 miles of line was 219. The average number of cars per 1,000 miles of line was 9,540. The number of passenger miles per passenger locomotive was 2,078,786. The number of ton miles per freight locomotive was 7,007,942. The aggregate number of locomotives and cars in the service of the railways was 1,848,260. Of this number 1,492,250 were fitted with train brakes, and 1,786,558 were fitted with automatic couplers. Practically all locomotives and cars in passenger service had train brakes, and of the 10,870 locomotives in that service 10,210 were fitted with automatic couplers. With respect to freight

RAILWAY ROUND-HOUSES

equipment most of the freight locomotives had train brakes, and 98 per cent. of them automatic couplers.

Locomotive building in the United States has reached that stage in its development when merely increasing the weight and size of locomotives for the railways to meet increasing weights of trains and severity of service does not suffice. It appears evident that to increase capacity, improve economy, and at the same time reduce injury to track a new development is needed. Already in Europe limits of size and weight in locomotives have been reached, and to meet analogous conditions in those countries the four-cylinder balanced compound locomotive has been developed into remarkably successful practice, especially in the principles of the de Glehn compound. To advance American practice by adapting to our conditions these principles, which have brought such advantageous results to European railways, is the object of the American Locomotive Company in its Cole four-cylinder balanced compound locomotive. It employs the principle of subdivided power; two of the cylinders (the high pressure between the frames) drive the forward or crank axle, and the others (the low pressure, outside of the frames) drive the second driving axle. In order to secure a good length for connecting rods without lengthening the boiler, the high-pressure cylinders are located in advance of their usual position. Special stress is laid on perfect balancing and the elimination of the usual unbalanced vertical component of the counter balance stresses, as a means for increasing capacity, improving economy of operation, and maintenance and promoting good condition of the track.

The question of properly loading locomotives has long since passed the theoretical stage, and it is now imperative to provide some practical and accurate method for obtaining the most economical results from operation. The putting of 125 per cent. on one train and 75 per cent. on another is not economical or in line with good practice, even though the average is 100 per cent. This condition exists on a majority of roads that do not provide for equating the tonnage of cars of different gross weight, and when engines are not properly rated. Some roads, when rating locomotives, take a given tonnage, say 2,000 gross tons, if in 65 cars, and the engine used its maximum power to haul it within the time allowed, that then becomes its rating. Now, when that same locomotive has 2,000 gross tons in 30, 40, or 50 cars, it is permitted to move over the road light loaded from 10 per cent. to 35 per cent., and in most cases is a net loss to the road so operating. It is impossible to build up all trains of equal average weight of cars; it is also impracticable to at all times place the heavy loads next to the engine, hence proper allowance must be made for each weight of car and its location in the train. The use of block signals has made it even more imperative that locomotives be not overloaded, for the reason that overloaded trains invariably stall on heavy grades, which, in turn, blocks trains following it on the same grade where they should have the benefit of momentum to assist them, but when stopped they frequently are unable to again get their train in motion, resulting in being obliged to double the hill,

delaying themselves, and possibly trains of a superior class.

It is well understood that the punishment inflicted upon cars and lading by current conditions in handling heavy-capacity cars in long trains with modern locomotives is a source of heavy loss, both in actual expenditure of money to make repairs and pay damages and in time lost by cars out of service. The real cause of this trouble was not so clear, however, until a dynamometer car was provided, capable of measuring the shocks and strains incidental to handling modern traffic. The recent West Seneca tests are in themselves sufficient to show the magnitude of these strains and the total inadequacy of existing spring gear to protect them, while the great capacity of the Westinghouse friction gear and the peculiar nature of the resistance employed, which enables it to absorb and dissipate serious shocks, is well illustrated.

It will be conceded that, directly and indirectly, the most vulnerable feature in the brake equipment of to-day is the hose connection, due to the fact that while designed to be *uncoupled* as well as *coupled by hand*, it is the pernicious but inevitable practice to pull them apart, thus injuring and ultimately destroying the hose, not to mention damage done to piping and consequent loss by leakage. Reliable statistics show that the automatic air coupler reduces cost of air-brake hose maintenance more than 50 per cent., while the saving in time required in making up or shifting trains is very great. The beneficial effect of this saving in crowded yards can hardly be estimated. Another time-saving appliance which is rapidly coming into use is the automatic brake slack adjuster. The adjustment of piston travel by hand is at best a slow process, and the results are generally unsatisfactory from the standpoint of economy in the wear of brake shoes, while the inequality of piston travel resulting therefrom produces an unevenness of braking effect in handling trains that might well be avoided. The automatic adjuster is a cheap and efficient remedy for these troubles.

The use of electric locomotives is becoming more extensive. For many different varieties of service they present features of economy, convenience, and safety that are rapidly bringing them into general favor. For mine haulage, electricity is by far the most convenient, flexible, and economical form of motive power. For light service on short railroads, for suburban freight and passenger traffic, for yard and tunnel service, for industrial haulage, power-houses, lumber yards, and plantations, it possesses many important advantages over steam.

HUGH T. DOWNING,
Mechanical Engineer.

Railway Round-Houses. The development of the steam railroad engine-house or round-house, as it is more commonly called, is coincident with the development of the railroad. It was sufficient, in the earlier days, to provide a house more as a protection from the weather than as a shop fitted with studied appliances for quickly and economically making locomotive repairs and attending to the regular routine work. As the development of the railroad called for specialists in its various branches, the round-house demanded its share of careful engineering

RAILWAY ROUND-HOUSES

to obtain the desired result of having each installation and its accessories arranged to best suit the local conditions.

The general principles which govern the planning of a round-house lay-out are: proximity to the car-yards; unobstructed connecting tracks; independent incoming and outgoing tracks; facilities on either or both of these tracks for supplying the locomotive with coal, sand, and water; facilities on the incoming track for taking care of ashes and clinkers; storage-room for the maximum number of incoming engines; and cross-over or auxiliary tracks to allow flexibility in handling any one engine as received on the incoming track in preference to others or to minimize the chances of a blockade due to accidents.

Construction.—Most engine-houses are round, hence the commonly used term. Pivoted at the centre of the house and usually in an open pit is the turntable. In regions of heavy snowfall this pit is often covered. Radiating from this centre are the tracks which enter the stalls of the house and also the incoming and outgoing tracks. The inner and outer walls of the house are, in their relation to each other, concentric polygons, with their diameters coincident. The diameter of the house is large or small according to the number of stalls that are desired in the completed circle, the inner circle being proportioned so that the door openings will be wide enough to amply clear the widest locomotive. General practice is to make these doorways 12 feet wide and at least 16 feet high in the clear opening. The distance from the inner wall to the outer wall for new houses is seldom made less than 80 feet and in many cases much more. Figuring for the longest locomotive to be handled, a sufficient space is left between the walls of the building and the ends of the locomotive to pass around the house and do the necessary trucking.

There are several prominent instances where rectangular and other special shaped engine-houses have been constructed. This plan is adopted either as an expedient to use to the best advantage all of a valuable piece of property or to have the building fit harmoniously into the general arrangement of other shops around it. Instead of being served by a turntable these houses make use of a transfer table or a set of fan-shaped tracks. For turning the locomotives a "Y" or a turntable is added.

In arranging the stalls of a round-house, care is taken to have opposite tracks match across the table. This little detail is of the greatest benefit in the operation of the house because it permits the handling of a dead locomotive by other locomotives under steam. If the tracks do not match, this cannot be done and much time is lost in moving the engine by hand.

Some sort of power device is generally used for turning the table. Electricity, compressed air, steam, and gasoline are employed according to the local conditions. When electric current can be depended upon at all hours of the day and night it is usually selected. Gasoline engines are preferable when an independent equipment is necessary. Compressed air and steam can be used to advantage but they are not as satisfactory.

Situated between the rails of the tracks in the house are the pits. These pits are for use

in getting at all parts of the running gear of the locomotive. They are made long enough to extend beyond the front wheels of the engine and the rear wheels of the tender. The usual length is from 50 to 60 feet, with the bottom sloping toward one end, in either direction, as best suits the drainage problem. The depth varies considerably, a fair average, however, is 30 inches at the shallow end and 36 inches at the deeper end. The pit floor is crowned in the centre, thus leaving a place as dry as possible for the men to stand on while under the locomotive.

A very important detail, from the operating standpoint, is the flooring of the house. This must be very substantial as well as impervious to water and oil, both of which are always present in large quantities. Experiments are being extensively carried on to determine what is the best floor to use, from which it appears that some form of concrete is the most satisfactory. Brick and cedar blocks as well as planking are also used extensively. The floor is arranged to shed the water as quickly as possible into the pits.

The heaviest service on the floor comes just outside the pits where lifting and jacking is done around the locomotive. With a view to strengthening this floor the sidewalks of the pits are sometimes made very wide so that the jacking can be done directly over them. Good heavy timber construction for this part of the floor is very serviceable.

Pipe outlets are arranged around the house so as to deliver compressed air, steam, and water to the spaces between the pits. The air and steam mains are ordinarily placed overhead with drop pipes for the outlets. At times, however, these mains are located in the same underground pit which contains the water mains. The pressure in the water main is maintained at least at 100 pounds per square inch. This pressure is utilized in washing out or cleaning the locomotive boilers of the mud and scale present, at times in large quantities.

Some sort of blow-off piping is ordinarily installed. The simplest plan is a main pipe connecting all the pits, from which there is a branch to each pit with a check and special fitting for connecting it to the boiler of the locomotives. The main pipe has an outlet through suitable catch basins and traps to the sewer.

In connection with the washing out of boilers, there are many more or less elaborate arrangements of pipes and reservoirs used, which have for their aim the saving of water and the conservation of the heat ordinarily wasted in the blow-off water.

The heating, lighting, and ventilating of engine-houses are problems which until recently have been only partially solved. Newer houses are constructed with the walls made, as far as practicable, of glass. The doors and even the roofs are also arranged to admit light. For night use, electric lighting is used, where possible. With a generous supply of plug outlets and extension lights, a model condition is obtained. The unsatisfactory oil torch and lantern are thus eliminated.

The heating and ventilating problems are being very successfully solved by the "hot blast" method of heating. This is the well known system of forcing heated air through ducts which

RAILWAY ROUND-HOUSES

distribute it advantageously throughout the building. For round-house use the particular advantages are in being able to concentrate a larger or smaller amount of hot air, as desired, upon the icy or frozen machinery of a locomotive and in supplying a large quantity of fresh air, continuously forcing out the gaseous and vitiated air produced by the fires in the locomotive boilers.

Machine Tool Equipment.—Very few round-houses of any importance are in operation which do not have some sort of machine tool equipment. The list contains, generally, a large and a small lathe, a planer, a shaper, a drill press, a bolt cutter, and an emery wheel. In case the house is not in touch with some repair shop, additional machines are installed, such as an air compressor, a dynamo, a wheel press, a wheel lathe, and drop pits. These, together with an assortment of air tools and the many special handy tools, permit of the heaviest running repair work being done on the locomotives.

Outside Facilities.—The outside facilities in connection with the round-house consist of the coaling station, the sanding appliances, the clinker pit, and the watering arrangements. These are ordinarily located on the incoming track between the storage track and the turntable. Their arrangement is varied to suit local conditions but, as far as possible, the clinker pit is placed close to the turntable. After the fire is removed from the grates it is very injurious to the boiler to handle the locomotive more than absolutely necessary, hence the clinker pit is located with this in view. The pit is some form of opening under the rails of the track into which the clinkers and ashes can be dropped. From the pit they are removed to the cinder cars for disposition along the company's right of way. A small pit is sometimes provided under the outgoing track for the cleaning of the ash pans of locomotives that are leaving the house.

Water is obtained directly from a tank by means of a drop spout or from a swinging stand pipe. Where conditions permit, this tank or pipe is located in connection with the sanding apparatus so that the locomotives can be supplied with one movement. The sand is supplied by gravity through a suitable pipe from an elevated storage bin. Before being stored it is dried or roasted so as to remove all traces of moisture.

The coaling station consists of some sort of elevated bin and a suitable spout to deliver the coal to the locomotive tender. Various types of coal chutes, as they are called, are used. A familiar form is the inclined track chute up which the loaded cars are pushed by a locomotive or hauled by a cable. The top of the chute where the cars are to stand is made level. The coal is removed into storage pockets. According to the type of chute, these are made large enough to hold several hundred tons of coal or small enough to hold a supply of coal sufficient for one locomotive.

In some installations, a combined coal chute, clinker pit, and sand tower is used. For this plan, a conveyer takes the coal from a pit under the coal supply track and deposits it in a hopper over the engine track. This hopper is supported on scales and autographic records are made of the coal delivered to the locomotives. This same conveyor also takes the ashes from the clinker pit to a storage bin from which they

are delivered to cars. The sand also is elevated to its special bin. With suitably located water supply this sort of installation is very economical of space. It also permits of the giving of all supplies as well as cleaning the fire with one "spotting" of the locomotive.

To take the place of a coal chute and a depressed cinder car track, locomotive cranes are often employed which are arranged with grab buckets. These cranes can take coal directly from the car and deposit it into the locomotive tender as well as pick up the ashes from the clinker pit and deposit them in the cinder car.

Organization.—A round-house is a scene of activity for all of the 24 hours of the day. The continued arrival and departure of locomotives, together with the routine work of repair and attention given them, requires an organization which must run with clock-like precision and at the same time must be capable of adjustment to abnormal conditions.

At the head of this organization is the round-house foreman, who is responsible to the division master mechanic. He also works in conjunction with the train dispatcher, having in view the getting of certain locomotives ready for service at the proper time for regular trains and others as soon as possible for extra trains. His particular duties are to distribute the work to the workmen and keep in touch with all that is going on in his domain. When the house is large and the amount of detail too great for the personal attention of one man, sub-foremen are appointed to have charge of such special work as machine repairs, boiler washing and inspection, engine dispatching, etc. These men take complete charge of the details assigned them and report to the house foreman.

The engine-men, on bringing the locomotive from the yards or station, leave it on the storage portion of the incoming track. The engineer looks over the entire machine, inspecting each part for defects and then makes a written report on a prepared form of what he finds wrong. He adds information concerning the boiler pops or safety valves, the injectors, the air pump, and other such special fittings.

The fireman attends to obtaining the necessary supplies, such as oil, waste, etc. It is customary in most instances for the engineer to leave a ticket for the amount of coal the hostler is to take on the tank. After leaving the locomotive the engineer registers in; that is, he fills out the register. Here he writes his own name, his fireman's name, his engine number, the train number, the time of arrival at the round-house, and all such train-operating information. Often he is required to show the hours that he has been on duty and the amount of rest that he is entitled to before he can be called for service.

The locomotive is taken from the storage track by the hostler and his helper to the coal chute, the sand tower, the water tank, and the cinder pit. The supplies are obtained and the fire cleaned before taking it across the turntable to the house. After reaching the stall, a second inspection of the machinery is made by a man trained to that special work. This man also makes a written report and the two records thus obtained must tally in important details. These work reports are used by the foreman or his assistant in distributing the work among the mechanics.

RAILWAY SECURITIES

A boiler maker enters the fire box and inspects and makes running repairs to the boiler, especially stopping all leaks as they are found in the flues and fire box. The smoke box at the front of the boiler is regularly opened and examined for defects in the spark-preventing devices.

At certain times, the periods varying according to the local water conditions, the locomotive boiler has to be washed out or have the water changed. If the latter course is pursued, the water is allowed to run out and the boiler filled with a fresh supply. If washing is done, the various washout plugs are removed and all the internal parts of the boiler thoroughly washed off. This is accomplished by the use of special nozzles of various sorts which will throw the high-pressure washout water to just the points desired.

Each mechanic, as his part of the work is finished, makes his "completed" mark on the engine condition board or on the locomotive itself. By reference to the board the foreman and the call boy can tell at a glance what locomotives are ready for service and approximately how soon others will be ready. As soon as definite information can be given as to the time that a "rounds" locomotive will be ready, the train dispatcher is notified. On his order, the engine-men are called and the locomotive sent to the yards.

Engine-men regularly assigned to certain trains are expected to be on hand in time to look over the locomotive, inspect all parts, see that all the necessary supplies are on hand, and take the locomotive either from the round-house stall or the outgoing track. If the train is unusually late the call boy is sent to advise them of the fact. The calling district is ordinarily within a radius of one mile of the house. Men on "rounds" engines or extra men, as they are designated, are always called. They are supposed to remain within the calling district and to advise the round-house foreman of their whereabouts. When called, the men are usually required to put their signature in the call book which the boy carries with him, and occasionally to add the time. Some organizations require a registering out as well as the registering in.

W. E. DUNHAM,
Mechanical Engineer, Chicago & North Western Railway Co.

Railway Securities. The capital required for even a relatively small railway is usually far beyond the amount which could be supplied by even the wealthiest individual or the largest group of individuals which could be satisfactorily included in a partnership. The legal device of incorporation is probably the only means so adapted to the requirements of railway finance as to provide the sort of capitalistic association necessary to the enormous railway development of the last 70 years. It meets not only the need for vast aggregates of capital, but also those for limited liability, centralized control and substantial continuity of management and policy. Consequently those who undertake railway enterprises invariably receive corporate securities in exchange for their contributions of capital and these, representing claims upon the property created and its earnings, are properly regarded as constituting liabilities of the cor-

poration. In the simplest form of financing a corporate enterprise the securities issued are all of one grade and participate equally in the distribution of the profits while having no other claim upon the assets of the corporation unless it is dissolved and its affairs wound up. Such securities are known as stock or shares of stock. In practice it has been found advisable to hold out different inducements to different classes of investors. Some investors are attracted by speculative proposals in which the possible gains are high, but the event doubtful, while others prefer lower returns if they are accompanied by greater certainty. The more conservative investors are therefore offered, according to their respective degrees of conservatism, preferred stock, non-cumulative or cumulative; income bonds; collateral trust bonds, equipment trust bonds, and mortgage bonds. Preferred stock is entitled to dividends at a certain rate before there is any payment to the holders of common stock and if it is cumulative the dividends not earned or paid during a particular year must be made up before there can be any dividend payments on the common stock. Preferred stock may or may not participate in further earnings beyond the rate for which it is preferred. Income bonds entitle the holder to a certain interest, provided it is earned. Collateral trust bonds usually rest upon the credit of the company issuing them and also represent pledged securities, commonly those of subsidiary corporations. Equipment bonds are issued to provide for the purchase price of new equipment, commonly paid for in annual or semi-annual instalments, and are secured by a lien upon such equipment. Mortgage bonds, as their name implies, represent indebtedness secured by mortgage upon all or part of the property of the corporation. Many railways have outstanding several classes of mortgage bonds of different degrees of priority. The following statement shows the par value of the securities of the different classes outstanding on 30 June 1902 and the proportion of each class to the aggregate representing all securities:

| | Par value | Percentage of total |
|--------------------------------|-------------------------|---------------------|
| Common stock..... | \$4,722,056,120 | 38.92 |
| Preferred stock..... | 1,302,145,175 | 10.73 |
| Miscellaneous obligations..... | 564,794,588 | 4.65 |
| Income bonds..... | 242,556,745 | 2.00 |
| Equipment bonds..... | 89,208,425 | .73 |
| Mortgage bonds..... | 5,213,421,911 | 42.97 |
| Total | \$12,134,182,964 | 100.00 |

It is important that the total par value of the securities shown above should not be mistaken for the actual capitalization of railway property. It is considerably in excess of the real capitalization, that is, the securities in the hands of the real owners (and creditors) of the railways, for railway corporations are themselves large owners of railway securities. The controlling corporations in large systems often own large blocks of the stocks and bonds of subsidiary corporations for which, in turn, they have issued their own shares or bonds. Consequently there is much duplication which must be deducted before the real capitalization, so far as the public is concerned, can be discovered. The railway shares held by railway corporations on 30 June 1902 had a par value of \$1,710,145,344 and the bonds so owned had a par value of \$498,373,449.

Deducting the total of these amounts, \$2,208,518,793, from \$12,134,182,964, leaves \$9,925,664,171, as the par value of the railway securities actually outstanding as against the railway system as a whole. It is interesting to observe that the total payment to the owners of these securities during the year which ended with 30 June 1902, was \$417,511,227, an amount which if capitalized at 4 per cent per annum would equal \$10,437,780,675 or within 5.15 per cent of the actual capitalization.

H. T. NEWCOMB,

Author of 'Railway Economics.'

Railway Shop Practice. Railway shop practice differs in many respects from methods in effect in the average manufacturing concern. This is especially true of the class and character of the work performed. In private institutions where the product consists largely if not entirely of new work, a single operation may be repeated over and over again. A factory making a specialty of the manufacture of bolts may construct a machine and supply it with a full equipment of dies to produce a certain size of bolt. The machine can then be operated up to its maximum capacity on this single product until it is worn to a point where it is rendered unfit for further service.

A locomotive plant, manufacturing new engines only, may so classify the work as to be able in almost every instance to confine the entire time of each machine to repeating a certain operation.

In the locomotive repair shop, however, on account of the wide range in the number of pieces and the small capacity of the average shop, such a variety of operations is required as to render necessary the accomplishment of many kinds of work on a single machine.

A 90-inch boring mill must be used to bore driving wheel tires, turn, bore and face cast iron and cast steel wheel centres, face locomotive front ends, turn and bore cylinder bushings, and so on. In like manner, a 42-inch boring mill will be required to bore eccentric straps, turn and bore eccentrics, face cylinder heads, turn, bore, and cut off cylinder and piston valve packing, and many other operations which in each case require special tools for setting and machining the work. One bolt machine will likely be used to head, and one thread cutting machine to thread all the different sizes of bolts for the plant.

Therefore, on account of the variety of the work to be considered, the scope of this article will cover certain rules, which, if carefully followed, should secure the maximum output of such average shop facilities as are to be found at present in connection with the various roads of the country.

The capacity of any shop depends as much or more on its official organization as upon the number of men employed. The discipline maintained in the shop during working hours and the relation of the foremen one to another are among the first subjects that will confront the shop superintendent, and which must be studied and mastered by him before he can hope to obtain results from the equipment and force in his charge.

Every railway repair shop is divided into certain departments, among which may be enumerated the erecting shop, or floor side; the

machine side, including the fitting shop, or vise work, and the tool room; the tin, pipe, and copper department; the blacksmith shop, boiler shop, paint shop, tank and truck shop, and carpenter shop. Under certain conditions there might be others, as the foundry, frog shop, etc., but this class of work will not be considered here. Each one of these departments should have an official head, and over all must rest the guiding hand of the master mechanic or shop superintendent.

A successful shop organization must be equal in all its parts, and the head of each department must be a manager of men as well as an observer of details. If the foreman in charge of a certain class of work is incompetent, inactive, or deficient in methods of discipline, or if he lacks a particular machine or device for quickly handling his part of the repairs, the output of the plant, no matter how well equipped every other department may be, will finally be measured by the number of engines which he is able to repair in a given time.

When capable men have been placed at the head of each department, the shop superintendent should then sustain them to the extent of his ability, holding them individually responsible for their duty to the company and their relation to the men.

The qualifications necessary to make up a well-rounded foreman are good health, judgment or common sense, honesty, determination, tact, energy, special knowledge of the work, and a fair education; and with his agencies, men and machines, he should work for results. He must plan his work ahead and see that each machine over which he has charge is supplied with the proper clamps, jigs, and appliances for doing the work, as well as proper cutting tools, and are used to set the work in the machine and cut the metal at the right speed and feed. This requires ability to take pains with little things and concentrate the necessary forces on a multitude of small things. Each machine must be kept clean and in good order, and to do this the foreman must be clean and neat himself.

The successful gang foreman must have executive ability which is nothing more or less than knowing how to distribute responsibility so that every workman not only accepts his share of duty, but continues unflinchingly to do it. If he accomplishes results, he must know how to make other people feel the trust imposed upon them, and to faithfully perform the part of work assigned to their charge. Every man in the shop must be held responsible for his work, which should be the required amount and of the proper quality, not because the foreman watches him closely, but rather from a pressure of a right conception of his duty to the company which should make itself felt throughout the entire shop.

Gang foremen, so far as it is possible, should be relieved practically of all clerical work. Their time should be spent with the men in teaching them quick methods and looking after such details as have a direct bearing on the output.

A constant supervision should be kept over the work of each department to see that it is quickly moved from one shop to another, or from one machine to another, and to see that each operation is being done according to the best known methods or on the machine best adapted to that particular work.

RAILWAY SHOP PRACTICE

The sole object to be sought, both by men and foremen, must be the greatest possible output of perfect finished work with the least delay and waste.

To accomplish this, the particular line of work in charge of each foreman must be systematized. There must be a certain routine way of doing things, and that the best way.

This one thing should be remembered, however, that system is not work, but a means of reducing the amount of labor necessary to produce a fixed product; system requires no specialists, but permits few to accomplish much by bringing brain and hand into intelligent action. It loads no man with labor beyond his proper share, but lightens the task of each by exactly defining it. The heavy load usually borne by a few faithful employees is distributed evenly upon all. Hard work always begins where system and the application of intelligent methods ends.

The Machine Shop.—The capacity of any locomotive repair shop depends largely, if not entirely, on the number and kind of its machines, but the introduction of the so-called high speed steels has had much to do lately with increasing the output of this department. The new steels have worked a revolution among machine builders generally; the old time lathes, boring mills, drill presses, planers, etc., are found to be entirely too weak to stand the great strain necessary to drive the new steel to its maximum capacity. The history of this comparatively new product had its origin in the introduction of the Taylor-White process of treating tool steel in the works of the Bethlehem Steel Company, in 1900. Hundreds of experiments were made by these two gentlemen, which finally resulted in producing a steel which is capable of producing in a given time two or three times as much work as any of the old carbon steels.

Another very gratifying result of these experiments is that they have awakened the management of railway repair shops, and the amount of work that can be done, even on the old machines, is a revelation to the entire mechanical world.

There are several brands of this steel, those in general use being Mushet's Special, and Allen high speed steel, which is an English product; Styrian or Bohler rapid steel, an Austrian product; Midvale, Novo, Rex, Zenith, etc. While some of these steels may be capable of greater endurance than others, any of them, under proper treatment, will be found superior in strength to any of the machines now in use, except those recently built. In using the high speed steel, however, it is not advisable to have too many different kinds in the same plant.

If the tool dresser is thoroughly familiar with one or two grades of high speed steel, and the quality is of such character as to produce results which will insure the maximum capacity of the machine, better results will be obtained by the adoption of these grades to be used in standard practice. No two high speed steels can be dressed and tempered exactly alike if the maximum output is desired, and if the tool dresser understands treating one of the standard grades correctly, the adoption of this make of steel will mean much time and money saved with better and more satisfactory results in the shop.

When these high speed tools are properly dressed and tempered, if it happens that the cutting edge is work, chipped, or crumbled away by very heavy feeds or speeds, after they are put into the machine the mistake of sending them back to the tool dresser should not be made if they can possibly be ground in the space of five or ten minutes, because if care is taken not to overheat them in grinding, they will be found to give much better results than when re-ground.

Some differences of opinion have existed, and perhaps always will, as to the proper feeds and speeds which should be maintained on the different metals, and no fixed rule can be laid down which will meet the requirements of all shops. The work varies somewhat in different shops. There is more or less difference in the construction of the parts.

The amount of metal to be removed and the accuracy of the work are also factors in determining proper feeds and speeds; but the fol-

RAILWAY SHOP PRACTICE

lowing table taken from the records of an average railway repair shop shows what should be done in the way of speeds and feeds on a machine of ordinary capacity. An average grade of high speed steel was used, and the condition of the tools shown at the end of each operation, is a fair representation of what should be accomplished in any shop with like tools and under similar conditions.

The preceding table shows the machine operation only. The time necessary to set the work will, of course, be determined largely by the facilities at hand for that purpose. With the exception of driving and truck wheel tires, cast steel wheel centres, and similar material, the following speeds can be maintained in roughing out work. A somewhat higher rate of speed may be used on finish cuts: Wrought iron and soft steel, 40 to 60 feet; cast iron, 60 to 80 feet; tool steel, 20 to 40 feet; brass, 120 to 180 feet.

These speeds, of course, may be affected both by the shape of the tool and the quality of the material. For long, continuous cuts on very hard cast iron, the speed should be reduced. Locomotive steel driving axles, rough forged, should be reduced to size ready for finish cut at a speed of 60 feet per minute, with $\frac{3}{8}$ -inch cut and $\frac{1}{4}$ -inch feed. Locomotive driving wheels, 44 inches to 84 inches in diameter, may be turned at a speed of 15 to 18 feet per minute, with $\frac{1}{2}$ to $\frac{5}{8}$ -inch reduction and $\frac{1}{8}$ to $\frac{3}{16}$ -inch feed. On the modern 50 horse-power 90-inch lathe these wheels should be turned out at the rate of five pairs in ten hours. A cylinder packing drum 18 to 24 inches in diameter and of sufficient length to make at least 12 rings should be set up and roughed out on a modern boring mill in about one hour. The finish cut should be taken with a broad-nose tool in about five minutes, including time to change tool. Piston rods, rough forged, should be roughed at a speed of from 60 to 80 feet per minute with $\frac{3}{16}$ -inch feed and $\frac{1}{8}$ -inch to $\frac{1}{4}$ -inch depth of cut. Cast steel engine frames should be planed at a speed of 20 to 30 feet per minute with a $\frac{1}{4}$ -inch cut, $\frac{1}{2}$ -inch feed.

These speeds and feeds can only be maintained on modern tools. On machines which have been in use for some time the speed and feed should be reduced to meet the conditions.

Planers.—Planers using high speed tools should maintain the following cutting speeds with a return per minute of about two to one.

| | | | |
|----------|--------------|--------|-----------------------|
| 20 x 20, | speed travel | of cut | 40 to 48 ft. per min. |
| 24 x 24, | " | " | 36 to 40 " " " |
| 36 x 36, | " | " | 32 to 36 " " " |
| 48 x 48, | " | " | 28 to 32 " " " |

If planers are powerful enough to pull the cut, the above speeds should work on wrought iron and soft steel as well as cast iron.

Lathe and Similar Cutting Tools.—The following sketches show what, in general practice, have been found to be the best shapes of cutting tools used in the principal operations of repair work:

The cutting qualities of a tool are governed largely by the shape of the cutting point or cutting edge. The principal conditions governing the shape of the tool are the kind of metal

RAILWAY SHOP PRACTICE

to be cut; the hardness of the metal; rough or finish cut; and manner in which tool is presented to the work.

For soft material, such as mild steel and wrought iron, the angles may be made much keener than when cutting harder metals. On materials that have a tendency to draw the tool in, as copper or brass, the angles may be made very blunt, often a negative take is given them. Tools for cutting soft iron and steel should be ground with sufficient keenness to turn long, curled shavings. The shaving is a good index with reference to the correct shape of the tool. When the shavings roll up in long curls, it is a very good indication that the tool is correctly ground and properly set in the tool post for the work; but if the shavings are crumbled and broken into small pieces, it indicates that the tool is improperly ground, or not correctly set to the work.

Either one or both conditions may be wrong. Tools used in taking heavy-roughing cuts should be given top rake sufficient to give a keen cutting edge the full depth of the cut taken.

In finishing cuts the amount of metal is not great, and most of the cutting is done with the point of the tool, in which case the top rake should be reduced. The position of the tool in the post will have much to do with the rake. For instance, the angle of top rake may be changed from front top rake to side top rake by changing the position of the tool as it is presented to the work.

If the tool is set with the point in advance of the tool post, care must be taken to see that it is firmly held, because if it becomes loose, it will "dig in" and is likely to spoil the work. If the tool post is set in advance of the point of the tool, there is little danger of serious results, should the tool become loose, as it will swing away from the work.

Tools for cutting iron and steel should be set as high as possible on the work, and always above the centre, while for brass it is best to grind the tool without any top rake and set it on the centre or slightly below the centre.

Cutting tools for machine operations, whether turning or boring, should be ground so that their rake or top angle will be sharp to the heaviest part of the chip. For instance, if a tool is to be used for facing the hub of a wheel, the part of the tool which first comes in contact with the iron should be a sharp angle, so that the heaviest part of the chip will flow easily away, while that part of the tool that leaves its mark on the finished face will take a shearing cut or angular shaving cut, and leave a smooth surface.

There is no more important point to be borne in mind by any one wishing to know how to obtain the best work from a machine than the cutting angles of the tools. In a general way every one knows that a tool should have as little clearance and as much top rake as consistent with the wear of the tool, but the man that makes the greatest record is the one that puts it into practice.

The next point is that no tool should be allowed to project beyond the holder or support more than is absolutely necessary. After the tools have been ground and set properly, they should have a chip or feed course enough to keep them from losing the edge in the vain employment of making thin chips—for if the chips are very fine it means that the tool has not only removed the metal but cut it into fine chips of no special value. Weak lathes generally do better work with a medium feed than a fine feed. A very fine feed is often used in trying to turn an extra true piece of work, with the result that the tool does not leave an even surface. It alternately "digs in" and "backs out" with a fine feed, when a medium feed would have resulted in an even steady cut.

Chattering frequently occurs because the chip or cut is not large enough to hold all the slack of the springing parts. More feed is usually the cure for chattering. Of course, chattering may be caused by a cut that is just heavy enough to balance the weight of the work and spindle, and then the slight necessary looseness of spindle bearings gives the chance for chattering. An old-fashioned remedy for this is to turn the tool upside down to get the pressure down on the work.

Chattering is destructive to the sharp edge of the tool and should be stopped as soon as noticed; but do not think a lighter cut is necessary, for frequently a heavier cut stops the chattering.

Facing cuts should be taken by tools with round shanks, for these can be turned so as to give the desired rake for free cutting.

In facing a piece in which the diameter of the cut in one place is two or three times its smallest diameter, make sure to take advantage of the change in speeds, for a very important reduction in time of operation as well as the durability of the tool may be effected by these changes.

Twist Drills.—The following table shows the revolutions per minute, and also the feed per revolution at which high speed twist drills can be run with safety. The revolutions mentioned are intended for wrought iron and steel and also for cast iron. On cast iron, however, it

| HIGH SPEED DRILLS | | | CARBON DRILLS | | |
|-------------------|----------|----------------|----------------|----------|----------------|
| Size of drill. | R. P. M. | Speed Per Rev. | Size of drill. | R. P. M. | Speed Per Rev. |
| 1/4 inch | 1050 | .008 | 1/4 inch | 450 | .005 |
| 3/8 " | 700 | .011 | 3/8 " | 300 | .005 |
| 1/2 " | 500 | .016 | 1/2 " | 210 | .007 |
| 5/8 " | 420 | .016 | 5/8 " | 160 | .007 |
| 3/4 " | 350 | .016 | 3/4 " | 140 | .010 |
| 7/8 " | 300 | .016 | 7/8 " | 130 | .010 |
| 1 " | 260 | .020 | 1 " | 110 | .010 |
| 1-1/8 " | 230 | .020 | 1-1/8 " | 100 | .010 |
| 1-1/4 " | 210 | .020 | 1-1/4 " | 90 | .015 |
| 1-1/2 " | 180 | .020 | 1-1/2 " | 75 | .015 |

will usually be possible, unless the metal is very hard, to exceed these speeds 20 to 25 per cent; and on brass the speeds may in most cases be doubled without injury to the drill. On the right will also be found a table of the speeds and feeds of carbon drills.

Carbon drills should seldom exceed 28 to 35 feet per minute on iron and steel and 60 feet on brass, measured on the circumference of the drill, and a feed per revolution of .004 to .007 for drill $3/8$ " and under in diameter. At these speeds and feeds it will be necessary to use plenty of oil or a solution of drilling compound when drilling steel, wrought, or malleable iron. It will also be found advisable to vary the speed somewhat according as the material to be drilled is more or less refractory.

High-speed drills may be run at a safe speed of 60 to 80 feet per minute on steel and iron, while no oil or drilling solution is required.

It has usually been considered good practice to grind the cutting edge of twist drills at an angle of 59 degrees, but recent experiments made with high-speed steel prove conclusively that an angle of 45 degrees will give equally good results with much less thrust on the drill. The following table shows the results of experiments along this line:

| | | | | | | |
|---------------------|-------|-------|-------|-------|-------|-----|
| Angle of drill..... | 37°.. | 45°.. | 50°.. | 55°.. | 59°.. | 65° |
| Thrust in pounds... | 215 | 225 | 220 | 260 | 290 | 325 |

These tests show that the thrust would be decreased by having more of a point on the drill. With an angle of 37 degrees, however, the drill would not stand up well on the work. At 45 degrees the drill stood up to the work as well as at 59 degrees and with much less thrust. The moment remains practically the same no matter what angle is used, so that the driving power does not change with the angle of the drill.

In order to obtain the best results from the use of high-speed twist drills it is necessary to observe carefully the following points:

1. Do not immediately run the drill at a very high rate of speed, but feed it slowly into the work at a good practical speed, allowing the drill to make one or two holes before driving it at its full capacity. This will prevent the sharp cutting edges of the drill from chipping out and also the point from breaking off. After the drill has become thoroughly warmed up to the work, the speed may be increased considerably without any danger of breaking the tool.

2. The drill should be run dry on cast iron and usually no lubricant will be required on iron and steel. If a lubricant is used at all it should be an ordinary soap and water compound or some of the compounds on the market for this purpose. Do not use plain water as a lubricant.

3. In grinding the drill do not press the point too forcibly against the stone as it may cause a number of surface cracks which in due time will cause the tool to break. On account of the very fine quality of the steel, much care should be exercised in grinding to insure maximum results from the drill.

Do not heat the drill to a high temperature in grinding as it will destroy the cutting quality of the steel.

4. The socket into which the drill fits should be in good condition and accurate in size so

that the drill will fit into it perfectly; otherwise the tang of the drill may twist off or the entire drill split to pieces through no fault of the steel.

5. On account of the high speed and feed at which these drills are operated it is necessary that the work be securely fastened, any slight movement of the work may destroy the drill. The work should never be held by hand.

Grinding Tools.—Lathe, planer, boring mill, and all similar tools should be carefully ground on machines built specially for the purpose, and one man or one set of men should be in charge of this work. When a machine man wants his tool ground he should give it to the man in charge of grinding and get another the same size and of exact shape, a stock of tools being always kept ground and ready for use.

This method guarantees uniformity in the shape of the tool and will result in a maximum output of the machine in which it is used. If the shop is large enough to warrant it, boys should be employed to deliver tools to and from the grinding room.

Methods of Paying for Labor.—Straight shop time or the hourly rate is still the most common method used in locomotive repair shops to pay for the services of the workmen, and this method is so well understood by all shop managers that explanation is unnecessary.

The contract system is used to some extent in paying for certain classes of repairs among which may be mentioned forging iron by the ton from the scrap for locomotive frames, rocker arms, piston rods, driving axles, etc. This consists briefly in agreeing with the leader of a gang of men to pay a certain fixed price per ton for taking the scrap iron or steel and forging it into such shapes as may be most readily worked into frames, axles, or similar parts. The leader of the gang employs such help as he thinks advisable to use on the work and pays a certain price, previously agreed upon, for the services rendered. In large shops this method may also be employed in turning driving wheels, overhauling pistons and rods, removing, overhauling, and replacing steam and dry pipes, etc.

Another method of rewarding labor is what is known as the differential rate system of piece-work. This consists in offering two different rates for the same job. If the work is finished in the shortest possible time and in perfect condition, a high price per piece is paid. If the workman is longer in performing the operation than the time which the job should take, or if there are imperfections in the work, he is paid a low price for his labor. The chief merits claimed by this system are reduced cost of output and increase in wages.

Accurate knowledge in rate-fixing which prevents any desire on the part of the workmen to "soldier" or hold back on the work in an endeavor to deceive the management as to the exact time required to perform any fixed operation. More uniform and just treatment of the employees resulting in a corresponding increase in the quality and amount of work. The selection of the best men for each class of work and the sifting out of those who are incurably lazy or inferior. The promotion of a most friendly feeling between employee and employer. This system readily adopts itself to the manufacturing concern, but on account of the great variety and

RAILWAY SHOP PRACTICE

complex nature of locomotive repairs it is little used, if any, for railroad repair shops.

Straight Piece-Work.—Beyond straight shop time, the straight piece-work system most readily adapts itself to the railroad shop, and is fast

venient for use by the shop specialist in timing all machine operations. This card is equally applicable to operations in other departments, in which case, of course, the speeds and feeds are omitted.

| B 322 | | Old, re-plane, both sides, D-1-2, each,..... | |

These sheets are bound in book form and put into the hands of the gang foreman and piece-work inspectors for permanent use in the shop. A letter is placed before the number of each operation to distinguish one department from another in timekeeping and accounting.

W. S. COZAD,
Shop Specialist, Erie Railroad.

Railway Shop Timekeeping. The system of timekeeping herein described, if intelligently applied, will meet all requirements in every department of a railway shop, whether on a day-work or piece-work basis. It may be handled entirely with cards, with the single exception of the time book. The cards can be made from a cheap grade of manilla cardboard and will be very convenient to handle both in the shop and office.

Checking Employees to and from Work.—Assume, as an illustration, that the shop employs 1,000 men. These men would likely be distributed among the different departments about as follows:

| | |
|---|---------|
| Erecting shop..... | 150 men |
| Machine and fitting department..... | 250 men |
| Boiler shop..... | 200 men |
| Blacksmith shop..... | 150 men |
| Tin, pipe and copper department, paint shop, carpenter shop, laborers, etc..... | 250 men |

To maintain a proper check on 1,000 employees, it would be necessary to establish check rooms or booths at perhaps four different points in the shop so that they will be easily accessible to the men and to allow proper handling of the cards within the limited time allotted for this purpose.

In this booth may be located a case containing about 250 separate departments as shown:

| | | | |
|------|--|--|---------|
| 1 | | | |
| 2 | | | 1-100 |
| 3 | | | |
| 4 | | | |
| etc. | | | 101-200 |

At each one of the points an opening may be made in the wall of the room similar to the window in a ticket office, and through this window the card shown in the illustration below should be delivered to and received from the men:

| | | | | | | |
| | | | | | | |
| | | | | | | |
| | | | | | | |

Correct: _____

Foreman. _____

RAILWAY SHOP TIMEKEEPING

One of these departments should be assigned to each employee and be so designated either by his name or number. In small shops where timekeeping is handled in the office of the general foreman, the departments on the right, numbered 1-100, 101-200, etc., can be used as a permanent file for piece-work cards.

At the end of each month, a sufficient number of cards (one for each day in the following month) should be stamped with the department, the employee's name, and placed in the proper "pigeon hole" in the case. This can be done with one blow of a rubber stamp with movable type, by having the block so constructed as to fit the blank spaces on the card. A bright, active boy can accomplish this work for 250 men in about two days.

The shop, office, or booth in which these cards are kept should be opened 15 minutes before the whistle blows and the person entrusted with this work must be on duty ready to give out the cards as the employees call their name or number—numbers are preferable because when a man leaves the service the person employed to fill his place can take the original number without any change whatever in the filing case. As each man passes the window arranged for this purpose and calls out his number, the card should be taken from his respective department in the case, the date and time of entering service stamped on it with a rubber stamp and passed out to him. At 12 noon the window is opened and the cards received from the men as they pass on their way out. During the noon hour the cards should be distributed in the case, and at 12.45 P. M. the window is opened again and each employee receives his card after the time at which he commences duty has again been stamped on it. This is his certificate to show that he was in the shop and ready for service at the time prescribed by the company. At 6 P. M. these cards should be collected at the window from which they were received by the workmen, approved by the foreman, and turned in to the office of the general timekeeper, where they should be properly entered in the daily time book.

At precisely 7 A. M. and 1 P. M. the windows should close, and any employee coming in after that hour may be required to apply at the office for the card, which should have marked on it in red ink the time at which he enters service. Any workman entering service without his "Daily Time Certificate" properly marked should be liable to lose the time for that half day, subject only to the discretion of the shop superintendent.

The card used to check employees in and out of shop will answer in every department of railway repairs, both cars and locomotives, in making daily record of all shop or day-work time.

The only difficulty to be guarded against in handling this work is in securing the proper charge. If the cards are allowed to pass unchecked by the gang foreman of the department, the men are liable to become indifferent and careless in fixing the exact number of hours against each engine or account where their work is of a miscellaneous nature. These cards should be carefully checked each day by the foreman in charge to obtain satisfactory results. In shops where a part of the time is on a piece-

work basis this should be recorded on the following card:

| | | | | | NUMBER | NAME |

Piece Work Checker

Foreman

To handle this card successfully it is necessary to have piece-work inspectors to inspect the work and use this card in making a proper record of the time. The piece-work inspector or time inspector as they are called in some shops should personally see each man who is paid by the piece, at least once a day, inspect the quality and amount of work which he has done, and by use of the schedule referred to on a previous page, make a careful record of the number of pieces and the price per piece, extending it as indicated on the card.

This inspection should be repeated day after day until the piece-work record card is full of items when either the total amount can be carried to the top of another card and the operation continued or the card may be totaled.

RAILWAY SIGNALS

properly signed, and turned in to the general timekeeper for entry in the time book.

time book may be printed according to the following illustration:

A. B. C. RAILROAD COMPANY PIECE-WORK

| | | | | | | | | | |
|------------------|-------------|-------|------|--------|------------------|-------------|-------|------|--------|
| Name _____ | | | | | Name _____ | | | | |
| Occupation _____ | | | | | Occupation _____ | | | | |
| Date | Card number | Hours | Rate | Amount | Date | Card number | Hours | Rate | Amount |
| | | | | | | | | | |

SHOP TIME

Day Rate _____ Per Hour

| | | | | | | | | | | | | |
|--------|------|--|--|--|--|--|--|--|--|--|----------|--------|
| Charge | Date | | | | | | | | | | Day rate | Amount |
| | | | | | | | | | | | | |
| | | | | | | | | | | | | |

The piece-work inspector should know his men and the position in which he will find them in going from one machine to another and from one gang to another in the shop and he should be provided with the necessary means in the foreman's office to arrange the cards accordingly.

When these cards are received in the office of the timekeeper they should be numbered consecutively from one up for each department, commencing with the first day and continuing through to the end of the month.

The above illustration shows a leaf of the time book for recording day-work and piece-work time.

Best results will be obtained by entering all shop time once each day, and in shops where charges to different accounts are numerous this book can be printed so as to use one page for piece-work and the opposite page for shop time; or, the book may be made large enough to provide ample room for both entries on same page.

In making out the monthly distribution of the various charges for work done in the different departments the form below will be found very convenient.

This sheet can be printed in a size to meet the requirements of the shop and a space left at the top of each column for the engine number or other charge. By the use of these sheets

DISTRIBUTION SHEET

Shop for _____ 19____

| | | | |
|---------|------|----------|-------------|
| Engines | Cars | Expenses | Shop Orders |
| | | | |
| | | | |

This book should be printed in a size which will meet the requirements of the plant.

The time recorded on the piece-work card should be entered in the book according to the card number and to the man who performed the work. Where two or more men work together on an operation covered by a piece-work price, the number of hours worked and the amount earned by each should be entered in each case against the card number.

In recording the shop time where the cards are turned in each day, the distribution of the different charges should be made when the time is entered in the book and the cards filed in a case arranged in alphabetical order so that they will be readily accessible in case of error or dispute.

A combination piece-work and day-work

the charges on the piece-work cards can be transferred as often as they are sent in from the shop, thereby distributing more evenly the office work through the month. **WM. S. COZAD,**

Shop Specialist, Erie Railroad.

Railway Signals. The subject of railroad signaling (with fixed signals) falls under three heads: the block system, concentration of switch and signal levers, and interlocking. The second and third may be considered as one. Block signals are used to maintain an interval of *space* between trains following one another. The regulation of trains by the maintenance of an interval of *time*, at stations, is imperfect because, if, in the case of a curved line or when the engineman's view is obscured by fog or falling snow, the foremost of two trains is unexpectedly stopped and delayed between stations.

RAILWAY SIGNALS

a collision may ensue in consequence of the negligence of a flagman or an engineman, or failure of lights or torpedoes. The block system at first was maintained by the employment of signalmen at each station, who, by telegraphing one to another, regulated the movement of the trains. The high cost of this system, due to the necessity of employing an attendant night and day at every station, led to the invention of automatic signals, which render the signalmen unnecessary. The large item of wages being saved, the block sections can be made as short as may be desired, thus increasing the capacity of the railroad by enabling trains to follow one another more closely.

The levers working a group of switches are concentrated, primarily, to save the time and labor of the switch tender, who otherwise must be continually running from one switch to another; but the principle is applicable, of course, to any number of switches within workable distance, say 500 to 800 feet; and at a city passenger terminus one man is able to attend switches which otherwise might require a half dozen attendants. The levers working the signals are of course likewise concentrated, and all are supported in a frame together. Interlocking is necessary where levers are concentrated, because moving a number of levers in wrong sequence may lead to a collision of trains. At a crossing of one railroad with another, for example, the attendant might inadvertently give clear signals on both of the lines at the same time. By locking the levers, one against another, so that he cannot do this, such an error is made impossible. At a drawbridge the signals controlling the movements of trains are interlocked with the apparatus by which the draw is locked in position. At drawbridges, and also at most crossings, a diverging track or a derailing switch is provided, so as to divert a train in case its engineman disobeys the stop signal.

The Telegraph Block System.—In this system, communications are made, in England, with apparatus like the needle telegraph, and in America with the Morse telegraph. A short code of signals by electric bells answers all ordinary purposes, and this is used in many cases. The telephone is also used to a limited extent, and is used as a convenience where the bell-code is the main reliance. The diagram (Fig. 1) represents the block signals at a single station, which we will call station *B*. The east-bound track only is shown. The principal sig-

nal may put signal *b* in the all-clear position and permit the train to enter the section between *b* and *s*. If the last preceding train has reached station *C* and has been reported clear of the block section *B-C* signal *s* may also be cleared, indicating that the road is clear to *C*. When both *b* and *s* are cleared, the distant signal, *d*, may also be cleared, but not otherwise. The distant signal, when its arm is in a horizontal position, indicates that the train must stop at *b*, but when the arm is inclined downward it indicates that *b* and *s* are both clear. In case of fog or snow-storm, or if the engineman's view is obscure in consequence of a curve in the line, this distant signal obviates the slackening of speed which otherwise might be necessary to enable the engineman to make sure of a clear signal at the home signal *b* before passing it. The signals referred to are semaphores, one of which, with a wooden post, is shown in Fig. 2. On American signals the arm or blade always extends to the right; in England to the left. The upper arm gives the indications, as just described, for the main line. The lower arm is to give indications for diverging tracks (supposing there were such a track at *T*, Fig. 1). The casting at the left hand end of the blade is fitted with a red glass spectacle for giving the "stop" indication at night. When the arm is inclined downward, to indicate all-clear, the spectacle is lifted, disclosing the white (uncolored) light, the all-clear signal. Where green is used for the all-clear indication at night, a double spectacle, with both red and green glasses, is provided. The counterweight *c*, one for each arm, serves to return the arm to the horizontal or stop position in case of breakage of the wires. On some railroads the semaphore arm is made to take any one of three positions: horizontal for stop, vertical for all-clear and half-way between, meaning "caution." On certain other roads the arm is inclined 45° upward from the horizontal to indicate caution. Where signals are required for two parallel tracks they may be set on a "bracket-post" as shown at *A* (Fig. 2). At *B* (Fig. 2) are shown home signals for movements in the same direction on two parallel lines, and distant signals for the same lines, the distant signals regulating the approach to home signals farther on. For low-speed movements, as from a siding to a main track, a dwarf signal is used (*C*, Fig. 2). Where signals are required for more than two tracks side by side they are usually set on a bridge spanning the tracks above the tops of the cars.

FIG. 1.—Signals at Block Signal Station.

nal, called the home signal, is shown at *b*. When a train is ready to proceed from *A* to *B* the attendant at *B*, receiving notice from *A*, replies, saying whether or not the line from *A* is clear as far as signal *b*; in other words, whether or not the last preceding train has passed wholly beyond *b*. If the line is clear, *A* then permits the train to proceed. If the line from *b* to *s* (the starting signal) is clear, *B*

Signals are further explained below, under *Interlocking*.

To provide against errors of signalmen, W. R. Sykes and others have devised electric controlling apparatus, so that to admit a train to a block section it is necessary to have the concurrent consent of the signalman at both the entering and the outgoing ends. This arrangement is called "controlled manual" or "lock-

RAILWAY SIGNALS

and-block." It is used on the London, Brighton & South Coast Railway and others in England and on the New York Central & Hudson River, the New York, New Haven & Hartford, and others in America.

FIG. 2.—Semaphore Signal 24 ft. high; arms in position to indicate "stop." C, counterweight; L, lamp. A—Signals on bracket post for trains moving in the same direction on two parallel tracks. B—Home and distant signals for parallel tracks; home for the section immediately in advance, distant for the section beyond. C—Dwarf signal, for slow movements.

Electric Train Staff.—For signaling on a single track railroad, where it is necessary to provide not only against collisions between trains running in the same direction but also between trains running toward each other, the apparatus of Tyer and of Webb & Thompson is used. In these a "staff" of wood or metal 20 inches long, or a round tablet about 3 inches in diameter, is delivered to the engineman as a

symbol to give the train the right to the track from station to station. Possession of this emblem assures the engineman that no other train is in that section. A magazine filled with staffs or tablets is provided at each end of a block section, and after one of these is taken out (at either end) no other can be taken out, at either end, until the first has been replaced at one end or the other. This control is effected by a lock, governed by a polarized electro-magnet. The magnets at the two stations are electrically connected by a wire, and withdrawal of a staff at either station locks both magazines, while the return of the staff to either unlocks both. The staff system is modified by a "permissive" staff or a staff with tickets; then two or more trains may follow one another in the same direction, while still the entrance of a train from the opposite direction is forbidden. A semaphore signal, giving permission to a train to enter a block section is in some cases interlocked with the staff apparatus, so that the signal indicates "stop" to entering trains until the staff has been taken out of the magazine and used as a key to unlock the signal. These single-track devices are used in England and Australia much more than in America.

Automatic Block Signals.—These are controlled by electro-magnets actuated by an electric current flowing through the rails of that portion of the track which constitutes the section to be protected. From a battery at the out-going end of the section the current flows through the right-hand rail to the signal at the entering end; thence through the coils of a relay at that signal, and back through the left-hand rail to the battery. The track being free from all vehicles, the relay is energized by the current; and by means of magnets, explained below, it holds the signal in the all-clear position. The presence of a train (or car) in the section de-energizes the relay by making a short path for the current, through the wheels and axis, from one rail to another, and this allows the signal to change by gravity from the all-clear to the "stop" position.

The connections for a simple automatic block signal circuit are shown in Fig. 3. The current flows from battery 12, at station C, through the rails on one side to station B, thence by a wire to the relay *r*, through its coils, and thence back to the battery by the rails of the other side of the track. At the ends of block sections (*a*) the rail-ends are insulated one from the other; and all the other rail joints are fitted with bond wires to insure a good electrical conductor throughout the section. At a switch, as at *v*, the track circuit is run through the rails of the side-track for a short distance so that if a car on the siding should be left standing so as to foul the main track, the current would be short circuited, throwing the signal to the stop position. As the insulation of the rails is poor, the battery for a track circuit must be of low intensity. The usual battery consists of two cells, gravity. In many cases the wire 13 by which the relay *r* controls the signal magnet *s* is extended, on poles, to the switch *v*, and to all switches in the section; and the setting of the switch for the side track is made to set the signal against approaching trains. In other cases the breaking of the track circuit at *v* is relied on for this. On a single-track railroad auto-

FIG. 9. INTERIOR OF SIGNAL CABIN.

Manual Switch and Signal Levers. The locking, back of the levers, is arranged in a horizontal frame. The arrangement in fig. 10 is for a vertical frame.

RAILWAY SIGNALS

matic signals must, of course, be arranged to give indications in both directions, and the relay of a given section not only controls the signal to which it is attached but also, by means of a wire run on the telegraph poles to the other end of the section, it controls a similar signal (on the other side of the track) at the far end, which gives indications to trains moving in the opposite direction. To provide against the possibility of a collision, in case opposing trains should enter a section from opposite ends at the same instant, the track circuit of each section is made to control not only its own signals but one other signal, farther off, in one direction, thus ensuring to at least one of the two trains the warning of two successive signals.

FIG. 4.—Union Automatic Clock-Work Block Signal. Disk, 20 in. in diameter, turning on vertical spindle. The cut shows the signal in the "stop" position; to indicate all-clear it is turned with its edge toward the approaching train. The lamp, turning with the disk, indicates at night white or green for all-clear, red for stop. The disk is made of loose slats to reduce resistance to the wind. The clock-work weight is suspended within the hollow iron post.

The actual movement of the signal is produced not by the track relay with its weak current, but by a weight and clockwork, controlled by magnet *s*; or, electro-magnet *s*, worked by a local battery, may itself be made powerful enough; or an electric motor may be used; or compressed air or gas. The clockwork, and the electro-magnet, were the usual sources of power until the demand arose for a larger signal. The clock-work signal, Fig. 4, is a disk 20 inches in diameter, turning on a vertical spindle.

The signal worked by an electro-magnet is a very light disk enclosed, to protect it from wind, rain and snow, in a case with a glass-covered opening. It turns on a horizontal axis (see Fig. 5).

For a large signal (semaphore) which cannot be protected from wind, rain and snow, compressed air was introduced as a motive power (see Fig. 6). For a series of signals an air compressor is provided at a central point which conveys pressure, through an iron pipe, either buried or above ground, to all of the signals along a section of 10 or 20 miles. Later, electric motors were adapted to this use, doing away with the expense and annoyance of the pipe, and substituting electric power for the compressor. The motor is worked by a primary battery and both motor and battery are usually contained in a box at the foot of the signal post (Fig. 7). A modification of this is the provision of storage batteries, charged through a power wire, conveying current from a dynamo situated at a central point; or, storage batteries may be taken out and carried to a charg-

ing station when exhausted. The electric motor is cheaper than compressed air, but further efforts to reduce cost and to supply each signal with a larger independent reservoir of power led C. J. Coleman to devise the liquid gas signal, in which the motive power is liquid carbonic acid gas, contained in a cylinder under high pressure. The cylinder is put in a pit at the foot of the post. A second cylinder (in the pit) is connected when the first is exhausted, and fresh cylinders are brought as often as needed. A reducing valve regulates the working pressure.

In automatic signaling the distant signals are usually fixed on the same posts with the home signals; for example, the distant signal for signal 11' section C-D is fixed on the post with signal 11, below home signal 11. Signal 11' may control the distant signal at 11 by a current through a wire run on poles, or by a pole changer which when signal 11' goes to the stop position, changes the polarity of the track circuit B-C. In place of relay *r* a polarized relay is used, the relay in its ordinary function controlling the home signal and on the polarized side controlling the distant signal.

On the Boston Elevated railroad, running very frequent trains, and with short block sections and trains of uniform length, an automatic stop is used. This is a device, fixed on the sleepers, working in unison with the block signal, which, when the signal is set to indicate stop, is moved into a position near the rail where it will strike a trip on the leading car and cause the air-brakes to be applied; so that any train which passes a stop signal is stopped in spite of anything that the motorman may do or neglect to do.

FIG. 5.—Hall Enclosed Disk Signal, 18 ft. high. The disk, which shows in the large glass-covered opening, is made of colored silk or celluloid, it indicates "stop." To indicate all-clear the disk is withdrawn from its position in front of the opening. The upper opening is for the night indications; a colored glass is in front of the lamp when the disk indicates stop and is withdrawn when the signal changes to "all-clear."

FIG. 3.—Automatic Block Signal Circuit. A section (B-C) is usually from 3,000 ft. to 5,000 ft. long; 10, 12 track batteries; 11, 11' automatic semaphore block signals, in position to indicate all clear; *r*, track relay; *s*, signal magnet; *v*, switch.

RAILWAY SIGNALS

To avoid the expense and complication of a distant and a home signal at every post, the three-position automatic signal was devised. In this, the semaphore arm when horizontal indicates stop, as with other signals; and when vertical it indicates proceed at full speed; but when it is at an angle of 45° , it indicates *stop at the next signal*, which makes it virtually a combined home and distant signal. As a home signal it means (in this last position) "proceed," but as a distant signal it means "stop" (at a point farther on). On electric railroads the rails of the track are used for the return of the powerful electric current used for the propulsion of the cars, so that an arrangement has been devised to control automatic block signals by the use of only one of the rails of the track. By the use of a polarized relay the difference in potential between the left-hand rail and the right-hand is made to control the signal magnet. This arrangement has not yet (1904) come into general use. The electric-light signaling apparatus used on electric railroads do not come within the scope of this article, as they lack important features which signal engineers deem essential to correct signal practice.

Permissive Block Signaling, as mentioned in connection with the electric train-staff, is practised under all of the different systems. With the telegraph block system, stations are usually 2, 3 or 4 miles apart, and when freight trains are unusually numerous, it often becomes necessary to run them nearer together than this, and so a permissive signal is given. The engineman running under such a signal must slacken speed, if necessary, at curves, or in case of fog, so as to avoid the possibility of striking any train ahead. With the controlled manual system the controlling apparatus is useless, if permissive

and there is no signman at hand to give positive information as to whether or not the last preceding train has cleared the block section.

Interlocking.—Fig. 8 shows two switches and four signals. To permit the passage of a train,

Fig. 7.—Automatic Semaphore Block Signal. The upper part of the box at the foot of the post contains the electric motor and controlling mechanism, the signal arms being moved by rods within the tubular post. The lower part of the box contains the battery for the motor, or, in the case of a gas signal, may contain the gas holders. Of the three glasses in each spectacle, the two upper ones indicate stop, taking the place of a single elongated glass; thus stop is indicated (at night) until the arm moves down fully to the all-clear position.

Fig. 6.—Electro-Pneumatic Semaphore Signal (short post to stand on overhead bridge). The signal arms are moved by vertical rods within the tubular iron post. The operating cylinder C is contained in the box A at the foot of the post. Admission of air to the cylinder is controlled by electro-magnet M.

signals are given. With automatic signals it is necessary to allow all trains to proceed permissively after having stopped at a block signal, because the signal may be indicating "stop" on account of some derangement of the apparatus,

say train No. 10, along the main line from *a* to *b*, the switch 3 in the main line track must be "straight"; switch 3, in the siding, must also be straight, so that any attempt to move from *c* to *b* (which would foul the path of train No. 10) will be thwarted; and signal 2 must be put in the all-clear or "proceed" position, giving notice to the engineman of No. 10 that the

RAILWAY SIGNALS

switch ahead of him is in the right position. The movement of the levers in this sequence is compelled by the interlocking. Lever No. 2 cannot be moved to clear the signal until lever No. 3 has been put in the right position; lever No. 3, working both switches simultaneously, cannot be moved until lever No. 4, working signal 4, is "home," in which position it must be when that signal is in the stop position, forbidding a train to proceed from *c* eastward. Near each switch there is a detector bar *g*, connected with the lever moving that switch, which prevents the signalman from carelessly changing the position of the switch while a car or engine stands over the detector bar. The bar lies close to the rail, on the outside thereof, and it must be lifted whenever the switch lever is moved; but the presence of a car-wheel will keep it from rising, and thus will prevent the movement of the switch lever. The signal at 1, with a fish-tail arm, is a distant signal, the function of which has been explained.

Switches are usually connected with the cabin or tower by iron rods (gas pipes) supported a few inches above the ground at short intervals on rollers; signals are connected either by rods or by wires. Bell cranks are introduced where it is necessary to abruptly change the direction of a rod. A long rod or wire must be provided with a compensator to obviate difficulty from expansion and contraction due to changes in temperature. For the rod, a simple

and electric machines have been devised to do the work. Where a manual machine requires, say, five men to work the levers, it is possible, by the introduction of power (which also saves steps by concentrating the levers in a smaller space), for one or two men to do the work. In the Westinghouse electro-pneumatic machine, compressed air, at 70 pounds per square inch, from a reservoir at the signal cabin, is conveyed in pipes, laid underground, to cylinders, one at each switch and one at each signal, in which the pressure, by means of a piston, moves the switch or signal. (A signal cylinder is shown in Fig. 6.) The admission of air to a cylinder is controlled by an electro-magnet fixed at its side, and the circuit of this magnet is controlled by a miniature lever (circuit-closer) in the cabin, the wires, like the pipes, being run underground. These little levers are suitably interlocked, the same as the large levers in a manual machine. The movement of a lever to work a switch does not, however, actuate the interlocking which releases the lever to be moved next; for the lever movement does not insure that the switch has actually been moved, it only closes the circuit. The next lever is held locked, until, by an electric current, the circuit of which is closed by the switch rails themselves, after their movement is completed, the "indication" of such completion is sent back to the cabin, permitting the unlocking of the next lever.

Following the introduction of the electro-

FIG. 8.—Interlocked Switches and Signals.

arrangement of levers, called a "lazy jack," is used. With a wire, the connection at the cabin must be readjusted as often as a change in temperature occurs. A number of more or less satisfactory automatic devices are in use for this purpose.

Where a number of levers are concentrated in a cabin, they are fixed on a common horizontal axis. One such lever is shown in Fig. 10, the axis being at *X*. The interlocking is effected, not by the lever, but by its latch *V*, so that the locking is "preliminary." For example, if the signalman starts to pull lever 3, to move switch 3, the preliminary act of unlatching it locks lever 4 before switch 3 begins to move. Lifting latch *V* moves a vertical rod or tappet *N*; this by means of a mitered dog, moves a horizontal bar in one of the grooves, *G*, a distance of about one inch, and thereby locks lever 4. If lever 4 were in the wrong position, it would obstruct the movement of the horizontal bar, and thus warn the signalman that he was attempting to pull the levers in the wrong order. The horizontal bars are made of any length necessary to reach the farthest lever in the frame, perhaps 50 feet, or more.

Power Switch and Signal Apparatus.—For the very numerous movements in a large yard, like a city passenger terminal, the working of switches and signals by manual power is laborious and comparatively slow, and pneumatic

pneumatic machine, the experiments of F. L. Dodgson showed that the electric current could be dispensed with by using air impulses to control the admission of compressed air to the working cylinders. Air is not so quick as electricity, but it answers all practical purposes at moderate distances. In his machine, the pressure in the power pipes is controlled by a valve, opened and closed by a leather diaphragm, which diaphragm is moved by air conveyed in a separate pipe. In this, the "all-air" system, the pressure in the cylinders is usually only 15 pounds per square inch, and in the small pipes leading to the diaphragm valves, it is only 7 pounds per square inch. The signalman's work consists in opening and closing valves by means of sliding bars (called "levers"); and the interlocking is the same as in other machines.

The "all-electric" switch and signal apparatus was developed by J. D. Taylor. A switch is moved by a one-horsepower electric motor fixed to the sleepers and worked by an electric current conveyed by wires from a dynamo or storage battery in the cabin. For a signal, a motor of one sixth horsepower is fixed to the signal post. The storage battery is usually charged by a generator run by a gasoline engine; and the amount of electric power used is so small that a small engine need be run but a few hours daily.

The machine in the cabin consists of a

RAILWAY, SINGLE RAIL TYPE

frame supporting horizontal sliding bars (called "levers"), each movement closing the circuit to a switch or a signal. The "levers" are interlocked, as in manual or pneumatic machines; and, as in other power machines, the interlocking is controlled by an "indication" sent to the machine from a switch after the switch has

FIG. 10.—Signal Lever and Interlocking Tappet. F, floor of cabin; G, groove for interlocking bar; N, tappet; V, latch rod.

actually completed its movement. This "indication" current is generated by the momentum of the switch motor, which is converted into a generator for a fraction of a second after it has completed its work of moving the switch. The movement of a switch requires a current of only seven amperes. Dwarf signals are worked by solenoids.

The railroads in the United States in 1904 aggregated over 200,000 miles. Of these lines, a length of about 4,400 miles was equipped with automatic block signals. Three fourths of this mileage is double-track railroad and about 300 miles is four-track. On about 22,500 miles of the railroads in the United States, trains run under the telegraph block system. In Great Britain and Ireland, all of the railroads carrying passengers are worked by the telegraph block system. On the continent of Europe, only the more important lines have the block system.

Automatic clock-work signals are used extensively in New England. The enclosed disk signals are used principally in New England and on the Lehigh Valley, the Philadelphia & Reading and the Chicago & Northwestern railroads.

Electro-pneumatic block signals are used extensively on the Pennsylvania Railroad; also on about 30 miles of the Central of New Jersey, and, for shorter distances, on the Burlington and other roads. Electric motor signals are used extensively on the Illinois Central, the Delaware, Lackawanna & Western and the Chicago & Alton, and are being introduced on many other roads. The electro-gas signal is in use on the Delaware, Lackawanna & Western, the New York Central and other roads.

The manual interlocking machines in the United States aggregate about 45,000 levers. The electro-pneumatic interlocking is in use at numerous points on the Pennsylvania railroad, at the two large terminal stations in Boston and at Chicago, Saint Louis and other cities. The "all-air" interlocking is in use at the Grand Central Station, New York, and at large stations in Chicago and other cities. The "all-electric" interlocking is in use at large stations in Chicago and at a large number of smaller places, this system being peculiarly adapted to places remote from a power station.

B. B. ADAMS,

'The Railroad Gazette,' New York.

Railway, Single Rail Type. An important development in railways is that known as

FIG. 1.—American Elevated Railroad System.

the single, central or monorail system. The first idea of a single-rail railway dates back to

RAILWAY, SINGLE RAIL TYPE

one hundred years ago, and many such are now being used in various parts of the world.

The first car run on a single rail, the invention of M. Charles Lartigue, has been in practical operation for many years in Djiboniti, a French African post. The car is kept vertical by its attachment to a laterally placed horse, which

FIG. 2.—The Cook System.

balances the car as a hansom is balanced by attaching the horse in front. The development of this primitive idea attracted the genius of all great civilized countries, and aided by government patronage, individual effort and fortunes, made great progress, but finally corporate wealth and American genius perfected on scientific lines a system which eliminates the possibility of derailment, makes the greatest speed attainable, with comfort, safety and economy.

Technically the system may be described as one where all the different resistances to a swiftly moving car or train, except the atmospheric resistance, are concentrated in the vertical plane of the centre of gravity of the car

FIG. 3.—The Tunis Monorail.

or train, being partially concentrated by centrifugal force, and those resistances which are not concentrated at the centre are nearly compensated for by friction removing devices. When the said body is at rest, or slowly moving, the unbalanced forces, only, are mechanically concentrated with a minimum friction, and the stability is positively and absolutely preserved without jarring movement. The downward vertical force consists of the weight of cars, trucks and load. This weight is delivered to, and directly sustained by, two centrally disposed bearing rails

laid with precision as to alignment and surface, and closely gauged to each other, so as to constitute practically a single support, while the vertical integrity or stability of the weight thus delivered to a central point is conserved when necessary by upward forces acting through the medium of dependent tension members, fitted with frictionless wheels bearing against inverted girders or rails; when moving at speed, stability is almost entirely preserved naturally and automatically, and only slight strain is on the dependent tension members. The magnitude of the downward forces is a matter simply of weight of cars; the upward forces are a matter of mechanical moments or leverages; the upward forces may amount to 10 per cent of the downward forces for usual cases. The downward force is delivered through the medium of the main central wheel, bearing on the two central rails as on a single rail. The side clutch wheels, that bear against the inverted girders or rails, guide, clutch and secure the car truck to its normal plane or path, forcing the truck to follow precisely any assigned in-

FIG. 4.—For surface street construction, showing overhead truck at the maximum height of 14 feet.

clination; for example, around curves. The central bearing rails and the inverted side clutch rails being laid with precision as to line, grade and inclination, the lateral and top-heavy swaying and recurrent oscillation now observable in locomotives in motion can never obtain; nor can the truck derail, as it is clutched to the track.

Upon the curves, the inverted rails are pitched (the one elevated and the other depressed) to an amount co-ordinate to the radius of the curve and speed. The lateral or tipping tendency of the trucks being always controlled, the car bodies resting upon the truck-bolster will have a base of support free of much pulsatory irregularity of motion now inseparable from moving cars.

The propulsion of cars is effected by electric

RAILWAY, SINGLE RAIL TYPE

motors, two or four motors to each truck, the number of motors being dependent upon the starting pull, acceleration and speed required.

The cars are mounted on two trucks; each runs on two bearing wheels, which follow the same central line; this mechanical sequence is economical of power, or draw-bar pull. The

mend, as overcoming many of the deficiencies of existing railroads and as marking a new departure toward the railroads of the future, with accompanying safety, comfort and economy."

While the monorail system is acknowledged to have reached its highest development in the United States and under the management of the American Elevated Railroad Company, yet no little credit is due to European endeavor and many American inventors. Among the American inventors whose efforts have attracted public attention should be mentioned Col. George S. Broot, of Washington, D. C.; E. Moody Boynton, of Massachusetts; Lina Beecher, of Batavia, N. Y.; William B. Mack, of Boston, Mass.; Howard Hansel Tunis, of Baltimore, Md.; Dr. Adolph Brodbeck, of the University of Nashville, Tenn.; L. F. Cook, and Dr. L. C. d'Hormergue, of Brooklyn, N. Y.

William B. Mack's design, shown here, appears to have been awarded more consideration among engineers than any of the many similar plans patented. As far back as 1872 a charter was granted in the State of New York for the building of a hanging railroad which had the general mechanical principles of the hanging roads more recently exploited in Germany, France, and Russia, but the Cook system, shown here, appeared to be the only serious effort made to date at hanging cars on the side of the structure in place of underneath.

E. Moody Boynton patented plans for a monorailway which were approved by such experienced railroad men as Austin Corbin. Several short test roads were built and operated. The Tunis plan here illustrated, is a modification of Boynton's. As will be seen, the single rail is laid on the ground like the rails of steam roads and trolley lines. Over the single rail at fixed intervals are trusses, or bents, joined

FIG. 5.—Behr System.

inverted rails do additional service as conductors of electrical currents by which the system is operated. This inversion of the charged rails avoids all the difficulties attending the operation of a third rail system.

This system solves the high speed problem, and makes possible the elevation of passenger, mail and express service from overcrowded standard gauge steam roads, converting non-

FIG. 6.—Behr System.

paying passenger traffic into the most profitable department of railroad business.

Concerning the monorail system of the American Elevated Railroad Company, described above, Mr. George H. Thomson, M. A. Soc. C. E., M. Inst. C. E., says: "After careful study, guided by years of experience in the location, construction, operation, and maintenance of railroads, I do not hesitate to approve and recom-

by cross pieces at the top and supporting the guides which prevent the car from toppling over. The car itself also embodies some unique and interesting features. It is narrower than the standard trolley or railroad car and rests on a single pair of wheels, or, in the full-size coach, on two trucks of two wheels each, arranged tandem, just under the centre of the floor, the platform and superstructure being balanced on

RAILWAY, SINGLE RAIL TYPE

them. The car is balanced on the single rail, the wheels being of the grooved pattern. So accurately are the weights adjusted that a slight lurch of the body will sway the car from side to side. At first some apprehension was expressed that in going around curves the centrifugal motion of the car would impose too great a strain on the bents, but this fear has proved wholly groundless. By allowing for the centrifugal force by the slant toward the inner side of the circle which is accomplished on ordinary roads by raising the outer rail the weight is thrown off the bents and approximately equalized. A road of this character is now in operation between Washington, D. C., and Wildwood Park, Md., a distance of forty miles.

The English monorail known as the Behr System, here illustrated, has been in operation for a number of years at Ballybunnion, Ireland, and was successfully tested by the Belgian government, securing a speed of 83 miles per hour with a car weighing 70 tons. In 1901 and 1902 the English parliament granted Mr. Behr's company the right to construct a road between Manchester and Liverpool, after the plans had been examined and approved by many eminent

FIG. 7.—Romanoff System.

engineers. The plans as will be seen by the illustrations, appear complicated.

The road is now being built, and will soon be in operation. It will extend from Manchester to Liverpool, and is patterned after the road which was operated at the Brussels exhibition in 1897, which was three miles long, and on which a speed of 83 miles an hour was frequently made. As this line was very crooked, it was not adapted to as high speed as the Manchester-Liverpool road, which has few curves.

The track is a single rail of the same shape and weight as generally used on steam roads. This rail is fastened at the top of an A-shaped structure made of steel. The structure is riveted to steel ties firmly imbedded in cement and rock ballast. The triangular supports for the rail are only 4 feet high, and one is placed every 3 feet 3 inches. At each side and 18 inches from the ground is placed a light guide rail to keep the moving car in position. The entire weight of the car rests upon large grooved wheels which travel upon the large rail at the top of the framework. As electric motors will be used to propel the train, each of these wheels will be made a "driver." Current is conducted on rails placed upon the ties, but insulated from them.

The car consists of two compartments, one on each side of the structure, and are 60 feet long, weighing four tons each. They will seat

32 passengers, who will sit with their backs to the track. No stops will be made between Manchester and Liverpool, and it is expected to make the trip of 34 miles in 20 minutes, which is just one half the best time now made by the steam road running between these cities. Two tracks will be provided, one for use in each direction, and only passengers, mail and light parcels will be carried.

The monorail idea has been exploited in Germany, France, and Russia in its application to hanging cars, but Germany alone has secured results. A suspended overhead railway system of rapid transit is now in operation between the three manufacturing towns of Vohwinkel, Eberfeld and Barmen, near Cologne, Germany. The road is built on a system of latticed longitudinal girders, one vertical and two horizontal, assembled into the form of an I-section. The main girders form the web of the I, and the lateral girders, which give the requisite lateral stiffness, serve as the top and bottom flanges of the I. Diagonal tie-rods extend from the upper panel points of the central girder to a connection with the chords of the bottom lateral girder. The last mentioned chords consist of steel I-beams, and upon their upper flanges is laid the single T-rail, from which the cars depend and on which they run. The girders, which vary in span from 21 to 33 meters (68.88 feet to 108.24 feet), are carried upon supports varying in structure with the locality where they are used. Where the railway is carried immediately above the Wupper River the A-frame style of pier is used, while in the towns through which the line passes the trusses are carried upon substantial U-frames. The A-frame consists of two rectangular latticed struts, which are united at the top by a rectangular plate yoke.

The supporting structure of the road, including trusses and piers, has an average weight of about 2,000 pounds per yard, which is due primarily to the great length of the girders and

FIG. 8.—Suspension Railway, Barmen, Germany.

unusual height of the supports at Elberfeld. Under more favorable conditions this weight could be reduced.

The cars are 37.7 feet long, 8.5 high and 6.88 feet wide; are therefore fairly long and narrow, and are slightly tapered at the ends.

They have a seating capacity of fifty, and are built with two side doors opening inwardly, and two auxiliary doors at the ends. The total weight of each car is twelve tons. The cars are freely suspended from two trucks spaced eight meters apart and having a diameter of 0.9 meters. The wheels are mounted in tandem to run on a single rail, and are driven by two electric motors of 36 horse power each, through

the medium of transmission gearing. The motor trucks receive current by means of a slipshoe and a contact rail, which is carried on the bottom of the lateral girder, somewhat to the inside of the main supporting beam.

The truck-frames embrace the rail-girders and the rails so closely that a play of seven millimetres is allowed and that derailment is impossible. If a wheel or axle should break the cars would be held up by the frames.

Oscillation of the car is limited by two projections on the lower part of the hook-shaped frame. The cars swing around the curve in a slightly inclined position and spontaneously re-assume their normal vertical position when a straight part of the rail is reached. To the passengers the change in equilibrium is imperceptible. Since a sudden change in equilibrium causes an oscillation proportionate to the velocity and the angle determined by the radius of the curve, which oscillation lies within twice the value of this angle, comparatively long transitional bends have been provided by reason of which the equilibrium is gradually changed, with the result that almost inappreciable oscillations are produced.

There are eighteen elevated stations on the line. This elevation was necessary in order not to interfere with street traffic in the towns. The rails run straight through the stations.

A Russian electric engineer named Hippolyte Romanoff has invented a monorailway of some merit. The invention consists of a monorail hanging car as shown here. The rails are supported by T-shaped columns, the carriages being suspended in the air and propelled by wheels running along the rails. These wheels are without flanges, which Romanoff asserts retard speed by clinging to the rails while rounding curves, but are prevented from leaving the rails by means of smaller wheels which grip the rails horizontally.

An electric feed-wire runs parallel with the rail. The cars have three supports each. If the first is broken the second comes into play automatically, and then the third. Should any one of the cars be stopped by an accident or for any reason other than the natural one of pausing at a station, all the cars behind would stop also, thus preventing any rear-end collisions.

In all the various applications of the monorail it has been fully demonstrated to the satisfaction of many of the world's most eminent engineers, that for speed, comfort, safety, and economy it excels any other form of railway yet devised.

Railway Surveying. See SURVEYING.

Railway Systems in the United States. *History.*—From the time of Hero, 2000 years ago, locomotion by steam has been the subject of much thought and experiment, but until Sir Isaac Newton proposed his steam carriage in 1680, there was little or no practical accomplishment. In 1769 the first self-propelled carriage was built by Nicholas Joseph Cagnot, a French army officer. This had two vertical single-action cylinders, and was the first known application of a high-pressure engine. From this time on there was continuous progress in

mechanical traction, and although the first locomotives were small and crude, their employment as an agent of transportation marks one of the world's greatest advances. The railways at the beginning were simple tramways equipped with tracks composed of wooden rails. Prior to 1809, Oliver Evans, of Philadelphia, urged repeatedly in public addresses the construction of a passenger railroad from Philadelphia to New York, and in that year attempted to form a company for this purpose. The State of New York, in April 1823, chartered the Delaware & Hudson Canal Company to construct a canal and railroad from the coal fields in Pennsylvania to the Hudson river at Rondout; the railroad, 16 miles long, from Honesdale to Carbondale, to carry coal, was completed in 1829. In 1826, the Quincy railroad in Massachusetts, four miles long, was built to haul granite to the port of Neponset; the rails were of wood, strapped with iron. In 1827, the Mauch Chunk railroad, nine miles long, was built in Pennsylvania to connect coal mines with the Lehigh river; the gauge was three feet seven inches, and the wooden rails were faced with iron. In 1826, the State of New York chartered the Mohawk & Hudson railroad, for freight and passengers, from Albany to Schenectady, 17 miles; work was begun in 1830, and the road was opened for travel in 1831. In 1827, the State of Maryland chartered the Baltimore & Ohio railroad. Work was begun in 1828, and in 1829 the track was finished six miles, and "cars were put upon it for the accommodation of the officers, and to gratify the curious by a ride." This was the first road in the United States that was opened for the conveyance of passengers; it was finished to Ellicott's Mills, 13 miles, in 1830. The Washington branch was opened to Bladensburg in July, and to Washington in August, 1834. The Charleston & Hamburg railroad, in South Carolina, was chartered in 1827. A locomotive was placed on it in 1830. The road was completed in September 1833, a distance of 135 miles. At that time it was the longest continuous line of railroad in the world. The track of the Baltimore & Ohio consisted of cedar cross-pieces and string-pieces of yellow pine 12 to 24 feet long and six inches square, with iron bars on them. The flanges of the wheels were on the *outside*. After some miles of this kind of road had been made, long granite slabs were substituted for the cedar cross-pieces and pine stringers. "Iron strips were laid for miles and miles on stone curbs." Before the road had been finished to Point of Rocks in 1832, "wrought-iron rails of the English mode" had been laid on part of the line. Many years passed before any other than flat rails were made in America. All the heavy rails were imported from England. Up to 1843 there were no facilities for the manufacture of heavy iron rails to supply the wants of the 4,185 miles of American railroad then existing, and of a few hundred additional miles then projected. The first heavy rails were rolled in 1844, of the U pattern, at the Mount Savage Iron Works in Maryland. The first T-rails made in America were rolled at the Montour Mill, at Danville, Pa., in 1845. The T-rail, now universally used on American railroads, is generally supposed to be of English origin, but it was invented by Robert L. Stevens, of Hoboken, N. J., in 1830, and was first

RAILWAY SYSTEMS

laid on the Camden & Amboy railroad. It did not come into general use until after 1845. The first made of these rails were only 16 feet in length. The first rails, 30 feet in length, were made at the Cambria Iron Works, at Johnstown, Pa., in 1856. The first 60-foot or double-length rails were rolled at the Edgar Thomson Steel Works, Pennsylvania, in 1875, and that company, in 1876, exhibited a steel rail at the Centennial Exhibition, 120 feet in length, weighing 62 pounds to the yard. See RAIL SECTIONS; RAILS AND STRUCTURAL SHAPES; ALUMINO-THERMICS.

The construction and development of the locomotive has kept pace with railway building in America. The English locomotives were expensive, could not be secured promptly, and were not well adapted to the light rails, steep grades, and sharp curves of the American tracks. Traffic conditions necessitated construction according to designs entirely different from those followed in Great Britain. Starting with Peter Cooper's one-ton locomotive, the *Tom Thumb*, which made its first run in August, 1830, between Baltimore and Ellicott's Mills, the locomotive has passed through every stage of development and enlargement, until now the designer stands between two fires. On the one hand is the motive power department calling for locomotives of ever-increasing tractive power; on the other hand, is the maintenance of way department setting a limit as to the weight of engine allowable. The two demands are largely contradictory, but the balanced compound locomotive gives relief in both directions. The economy gained by compounding gives greater power per unit of weight of engine, and the perfect balancing of the moving parts gives an engine which, compared weight for weight with a single expansion, is very much easier on the track. Traffic requirements are still calling for rolling stock of greater capacity and the monster 400,000-pound locomotive must continue to grow until the highest factor of efficiency and lowest possible ton-mile cost of haulage is reached. See LOCOMOTIVE, THE; LOCOMOTIVE ENGINE; LOCOMOTIVE AND ENGINE INDUSTRY; LOCOMOTIVES, COMPOUND.

The gold of California gave great impetus to railroad projects until the commercial crisis of 1857 and the Civil War seriously interfered. With the return of peace, however, there was a marked revival. The transcontinental route over the Union Pacific and the Central Pacific roads was opened in 1869, and construction then became most active in the Northwestern States. A similar revival followed the crisis of 1873. By 1880 the principal field of activity was in the Southwestern and Rocky Mountain regions and in 10 years, to 1890, the railroad mileage of the country had increased from 93,000 to 164,000 miles. Each section of the country, as it filled up with competing roads, witnessed a period of secret rebates and receiverships and the gradual consolidation of intermediate links into long lines occupying the principal thoroughfares and controlling their own feeders. The consequent stifling of competition early led to the establishment of State commissions and the Interstate Commerce Commission. (See COMMERCE, INTERSTATE.) The vigorous campaign against the Commission has been carried into the Supreme

Court with indecisive results—and the war is still on.

Railway Groups.—The railway system of the United States, as a whole, may be divided into groups, each group occupying a distinct section of the country. (See AMERICAN RAILROADS.) This classification gives little information regarding ownership and management. The following tabulation, influenced by community of interest or harmony of action, shows the present progress of groupings of systems. These groups are not antagonistic, but are rather intertwining circles of influence and control, all being irresistibly drawn toward a common centre:

| | MILES. |
|--|---------|
| Morgan | 26,393 |
| Vanderbilt | 20,520 |
| Vanderbilt-Morgan | 7,877 |
| Pennsylvania | 16,675 |
| Pennsylvania-Vanderbilt-Morgan | 4,746 |
| Harriman-Hill-Morgan | 20,187 |
| Harriman | 23,051 |
| Seaboard Air Line | 2,625 |
| Rock Island | 14,966 |
| Gould | 16,527 |
| Atchinson | 8,615 |
| St. Paul | 6,682 |
| Minneapolis-St. Louis | 3,118 |
| Missouri, Kansas & Texas | 3,005 |
| Pere Marquette | 2,351 |
| Chicago Great Western | 1,464 |
| Wisconsin Central | 1,043 |
| Aggregate | 179,845 |

The lines in the Morgan group are the Southern (including the Mobile & Ohio, 874 miles), 9,302 miles; the Atlantic Coast line (including the Louisville & Nashville, 6,133 miles), 10,703 miles; Central of Georgia, 1,877 miles; Chicago, Indianapolis & Louisville, 556 miles; the Lehigh Valley, 1,399, and the Erie, 2,556 miles.

The Vanderbilt group includes the New York Central (with the Lake Shore, 1,411; Michigan Central, 1,653; "Big Four," 2,235; "Nickel Plate," 523, and the Lake Erie & Western, 725 miles), total, 11,079 miles; also Chicago & Northwestern, 8,971 miles.

The Vanderbilt-Morgan lines are the Delaware, Lackawanna & Western, 824 miles; Delaware & Hudson, 966; New York, New Haven & Hartford, 2,037; New York, Ontario & Western, 549; Boston & Maine, 3,298, and the Pittsburg, Bessemer & Lake Erie, 203 miles.

The Pennsylvania group includes the Pennsylvania system, 10,566 miles; the Baltimore & Ohio, 4,397, and the Norfolk & Western, 1,722 miles.

The Pennsylvania-Vanderbilt-Morgan lines are the Chesapeake & Ohio, 1,641 miles; the Reading, 2,145, and Hocking Valley, 960 miles.

The Harriman-Hill-Morgan roads are the Great Northern, 5,888 miles; Northern Pacific, 5,976, and the Burlington, 8,323 miles.

The Harriman group are the Illinois Central, 5,463 miles; Chicago & Alton, 915; Chicago Terminal Transfer, 108; Kansas City Southern, 839; Union Pacific, 6,105; Southern Pacific, 9,621 miles.

The Rock Island group includes the Rock Island, 7,298 miles; St. Louis & San Francisco, 5,663; Chicago & Eastern Illinois, 752; Evansville & Terre Haute, 331, and lines in Texas, 922.

RAILWAY SYSTEMS

The Gould group includes the Missouri Pacific, 6,006; Texas & Pacific, 1,973; Denver & Rio Grande, 2,460; Saint Louis Southwestern, 1,511; International & Great Northern, 1,130; Wabash, 2,483; Wheeling & Lake Erie, 520; West Virginia Central & Pittsburg, 177, and Western Maryland, 258 miles.

These groups are growing lesser and lesser while the consolidation process is going rapidly on. Should all the interests come together, the gigantic combine will crumble of its own weight, as did many of the railroad systems so elaborately built up 20 years ago. The wisdom of the present may not see the remedy, but earnest thinkers look upon government control or regulation of railways as the only way to establish and maintain equitable relations between the carriers and the people whom they serve.

Ownership.—The actual ownership of American railway securities is vested in about 350,000 people, these holdings ranging from a few shares to more than 40,000. The control of the roads, notwithstanding the ownership through stockholdings distributed among such a large number of individuals, rests with fewer than a score of people representing four or five of the great business houses on Wall street. The following table shows the number of stockholders of record of 30 important railways of the country:

| NAME OF COMPANY. | NUMBER OF STOCK- HOLDERS IN 1904. |
|--|--|
| Pennsylvania | 44,175 |
| Atchinson, Topeka & Sante Fe | 17,823 |
| Union Pacific | 14,256 |
| New York Central & Hudson River | 11,872 |
| New York, New Haven & Hartford | 10,842 |
| Southern | 9,572 |
| Illinois Central | 9,123 |
| Boston & Albany | 8,417 |
| Boston & Maine | 7,402 |
| Baltimore & Ohio | 7,132 |
| Fitchburg | 6,099 |
| Chicago Great Western | 5,977 |
| Chicago, Milwaukee & St. Paul | 5,832 |
| Lehigh Valley | 5,777 |
| Old Colony | 5,371 |
| Erie | 4,309 |
| Chicago & Northwestern | 4,109 |
| Delaware & Hudson | 3,819 |
| United New Jersey | 3,585 |
| Norfolk & Western | 2,911 |
| Denver & Rio Grande | 2,910 |
| Pittsburgh, Fort Wayne & Chicago | 2,642 |
| Morris & Essex | 2,450 |
| New York, Ontario & Western | 2,437 |
| Southern Pacific | 2,424 |
| Concord & Montreal | 2,356 |
| Boston & Lowell | 2,168 |
| Northern | 2,068 |
| Cleveland & Pittsburgh | 2,041 |
| Chicago & Alton | 2,039 |

The following 27 companies each have stockholders ranging between 1,000 and 2,000, as follows:

| NAME OF COMPANY. | NUMBER OF STOCK- HOLDERS. |
|--|---------------------------------|
| Pere Marquette | 1,984 |
| Mine Hill & Schuylkill Haven | 1,974 |
| Wabash | 1,974 |
| Cleveland, Cincinnati, Chicago & St. Louis | 1,065 |
| Missouri Pacific | 1,861 |
| Louisville & Nashville | 1,672 |
| Atlantic & St. Lawrence | 1,661 |
| Boston & Providence | 1,654 |
| Delaware, Lackawanna & Western | 1,575 |
| Cincinnati, Hamilton & Dayton | 1,558 |
| St. Louis & San Francisco | 1,521 |
| Missouri, Kansas & Texas | 1,509 |
| Hocking Valley | 1,503 |

| NAME OF COMPANY. | NUMBER OF STOCK- HOLDERS. |
|--|---------------------------------|
| Chesapeake & Ohio | 1,478 |
| Vermont & Massachusetts | 1,313 |
| Northern Central | 1,196 |
| North Pennsylvania | 1,100 |
| Rome, Watertown & Ogdensburg | 1,094 |
| Huntington & Broad Top | 1,072 |
| New York, Lackawanna & Western | 1,070 |
| Little Miami | 1,064 |
| Rutland | 1,058 |
| Chicago, St. Paul, Minneapolis & Omaha | 1,045 |
| Utica, Chenango & Susquehanna Valley | 1,042 |
| Georgia Railroad | 1,038 |
| Philadelphia, Germantown & Morristown | 1,035 |
| Wheeling & Lake Erie | 1,004 |

The value of railroad securities held by insurance companies, saving institutions, and educational institutions, exceeds \$1,500,000,000, and inasmuch as these fiduciary holders represent large bodies of individuals and some holding companies whose own shares are widely distributed, it is readily seen how materially the business life of the nation is based upon railroad values and how widely diffused is the railroad ownership. See RAILWAY RECEIVERSHIPS AND REORGANIZATIONS; RAILWAY SECURITIES.

Mergers.—The permanent control of a railroad corporation may be accomplished by depositing a majority of its stock with a holding company. This plan is utilized as an indirect means for the consolidation of several companies, by the ostensible sale of sufficient shares of each company to a corporation formed for that specific purpose. This device has been expanded, in the notable instance of the Northern Securities Company, to controlling the operation of rival lines extending from Chicago to the Pacific ocean. In the spring of 1901, the Northern Pacific Railway Company and the Great Northern Railway Company, two roads which were regarded as parallel and competing lines, united in purchasing nearly the entire capital stock of the Chicago, Burlington & Quincy Railway Company, becoming joint sureties for the payment of the bonds of the Chicago, Burlington & Quincy Railway Company, whereby the purchase was accomplished. In November, 1901, the Northern Securities Company was organized under the laws of the State of New Jersey, with a capital stock of \$400,000,000. Shortly after its organization that company acquired a large majority of the stock of the Northern Pacific Railway Company, and also a majority of the stock of the Great Northern Railway Company, paying for these stocks with its own stock. A suit was brought by the United States against the Northern Securities Company in the Circuit Court of the United States for the circuit of Minnesota. On 9 April 1903, that court held that all the stock of the Northern Pacific Railway and Great Northern Railway Companies held and owned by the Northern Securities Company was acquired in virtue of a combination or conspiracy in restraint of trade prohibited by the Sherman Antitrust Act. Its officers, agents, etc., were enjoined from voting the aforesaid stock, or from attempting to vote it at any meeting of the stockholders of either of the railway companies, etc. The decree, however, allowed the Northern Securities Company to return and transfer to the stockholders of the Northern Pacific Railway and Great Northern Railway Companies,

RAILWAY SYSTEMS

respectively, all the shares of stock in either, which the Northern Securities Company had received in exchange for its own stock. An appeal having been taken from this decision to the Supreme Court of the United States, that court on 14 March 1904, affirmed the decision of the lower court. See RAILWAY CONSOLIDATION.

Valuation of Railways.—The aggregate railway capital in the United States on 30 June 1904, as measured by the par value of outstanding securities, was \$13,213,124,679, which shows a capital of \$68,553 per mile of line, including liabilities. In arriving at the actual valuation of railways, well-defined rules are followed: (1) Inventory valuation applies only to a limited degree. (2) Income valuation is the only true basis of calculating a railroad value. Every item of assets, except those of a distinctly detachable character, is contributory to the general income account and gets its value there. (3) Cost of duplication is only discussed where the line is obviously obsolete in standards of grade and curvature and where the menace of competition at less cost by a better-equipped rival is real. (4) The property accounts of road and franchises are only indirectly considered on the basis of net stock and debt capital per mile of line set against like figures of competitors in the same territory. Questions of actual investment and past costs are practically ignored. The whole consideration is limited to present and future earning power under present and future competitive conditions. Competitive pressure is not supposed to be applied at the maximum at every point; that is, every mile of road is not revalued at an estimated cost of present duplication by a parallel construction under most modern and most favorable conditions. As a practical proposition such duplication is recognized as financially impossible. It could only occur at certain places. Because it may be good enterprise and socially economical to parallel 500 miles of line at present cost of duplication, it does not follow that it is good enterprise and socially economical to do the same for 15,000 miles. The possibility of actual competition for the 500 miles cannot apply with equal force as potential competition to reduce the value of the remaining 14,500 miles.

Gross Income and Its Application.—The total railway capital of the United States in January, 1906, was \$10,973,524,903. The gross income of \$1,900,846,907, for the year 1905, was applied as follows:

| | |
|---|---------------|
| Pay of employees..... | \$775,321,415 |
| Fuel for locomotives..... | 146,509,031 |
| Oil, etc., for locomotives..... | 7,708,642 |
| Taxes..... | 57,849,569 |
| Permanent improvements..... | 41,948,183 |
| Deductions and deficits in weak lines.... | 44,681,341 |
| Locomotives, renewals and repairs..... | 50,000,000 |
| Freight car renewals and repairs..... | 50,000,000 |
| Passenger car renewals and repairs..... | 15,000,000 |

Equipment and Employees.—Enormous quantities of rolling stock are required to equip the 212,000 miles of railway in the United States. Locomotives number 41,000, of which 10,000 are in passenger service, 24,000 haul freight, and 7,000 are required for special service. There are 37,000 cars needed to move passengers, and 1,600,000 cars to carry freight. (See CAR BUILDING INDUSTRY; STEEL CAR INDUSTRY.) Were all these engines and cars in use at the same time there would be a passenger train for every 21 miles of road in the United States, and a freight train for every nine miles. End to end the passenger equipment would make a solid train 500 miles long. The freight cars and engines would make another train about 9,000 miles long, or nearly three times the entire distance from the Atlantic to the Pacific. A thousand million miles is covered by the various trains during the year—450,000,000 by passenger trains and 550,000,000 by freights. The mileage of the individual freight cars makes a distance inconceivably great. They run far enough to girdle the earth at the equator each minute, day and night, every day in the year, or an aggregate of 40,000,000 miles a day and over 14,000,000,000 miles a year.

The freight trains of the nation carry 1,250,000,000 tons of goods during the year in an average haul of 135 miles per ton. This means that they transport a total of about 170,000,000,000 ton miles. With every second of time the railroads do enough work to transport a ton of goods 540 miles, or half the distance from New York to Chicago. It would take 25,000,000 teams and their drivers to do as much. The work performed by the railroads, if done in the old way, would require two and a half times as many horses and mules as there are at present in the entire nation, and practically the entire male population over 15 years old. On the whole, so enormous are the demands of our modern civilization, that to feed, clothe, shelter, and provide the various needs and luxuries of the people requires the transporting of a ton of goods 280 miles every week in the year for each family of the nation. The railroads charge the enormous sum of \$1,250,000,000 a year for doing this work. Yet this is only three-fourths of a cent for carrying a ton of goods a mile. This estimate does not take account of the passenger service. The railroads take toll amounting to \$400,000,000 a year for carrying passengers. But to earn this money they transport 700,000,000 passengers an average of 30 miles each. This is an aggregate of 21,000,000,000 passenger miles a year, or 700 miles with every stroke of the clock. The railroads thus average about two cents a mile for each passenger carried. See RAILWAY TARIFFS; RAILWAY (ELECTRIC) ECONOMICS; RAILWAY INTERCHANGE CAR SERVICE.

To carry on this enormous traffic requires an army of 1,250,000 men, and their yearly pay

RAILWAY SYSTEMS

aggregates \$750,000,000. Among these workers are 10,000 presidents, vice-presidents, general managers, and other general officers, and 40,000 general office clerks. There are 35,000 station agents and 110,000 other station men. There are 30,000 telegraph operators. The care of tracks requires 35,000 section foremen and nearly 300,000 track walkers. Watchmen, flagmen, and the like, number 50,000. To keep the trains and buildings in order requires 40,000 machinists, 50,000 carpenters, and 140,000 other shop men. The actual running of the trains requires 225,000 men, or about one in every five of the total number of railroad employees. Of the men 50,000 are engine men and as many more are firemen. There are 35,000 conductors and some 90,000 other trainmen.

Safety Devices.—In the last few years the phenomenal increase in tonnage hauled on American railways has necessitated the purchase of more and better engines and cars of larger capacity, equipped with the best safety devices. Enormous sums have been expended in taking out curves, cutting down grades, laying additional main tracks, putting in new sidings and providing improved terminal facilities. (See RAILWAY ENGINEERING; STREET RAILWAY CONSTRUCTION; RAILWAY PASSENGER STATIONS.) But, notwithstanding all these improvements, many lines find it impossible to handle their business with sufficient dispatch to avoid congestion. This fact has led many progressive American railway managers to realize that if they are to secure the best and most economical returns from the great expenditures made for motive power, car equipment and tracks, suitable means must be provided to enable their trains to move with a minimum of delays and a maximum of safety; and this can only be realized when train orders are supplanted by an up-to-date block system and hand-operated switches by a modern system of interlocking.

The very highest development of the art of signaling has been reached in this country, but no American railway line is nearly so thoroughly equipped with signaling as is the average English line. (See RAILWAY SIGNALS.) The first interlocking plant installed on the London and Northwestern railway was put in service in 1859; 14 years later, in 1873, there were in use on that line alone 13,000 levers. At the same date there was not a single interlocking plant in use in the United States, the first plant in this country having been installed in the year 1874, at Spuyten Duyvil Junction, in New York city. At the present time there are in use on the 1,800 miles of line of the London and Northwestern railway approximately 36,000 interlocked levers, or an average of about 20 levers per mile of line, whereas there are only about 40,000 in use on all lines of the United States, or, approximately, one lever to five miles of line.

The tests recently made at West Seneca, N. Y., have served to demonstrate the net results attained in providing brakes and draft gear fully adequate for service under modern conditions, and to perfect other new devices no less important from an economical and operating standpoint. During the 15 years that have elapsed since the quick-action automatic brake came into general use on freight trains, the average weight of locomotives on drivers has

increased from 100,000 to 200,000 pounds, and their draw-bar pull from 25,000 to 50,000 pounds. Within the same period the average freight car capacity has increased from 40,000 pounds to 100,000 pounds; and while in 1888 50 cars in a train was considered a maximum, now 80 is common and 100 by no means rare. Reference to these figures is scarcely needed to emphasize the statement that brake apparatus which met all requirements 15 or 20 years ago is now satisfactory only in inverse proportion to the increased demand made upon it. So far as draft gear is concerned the proposition is self-evident.

Port Differentials.—The Atlantic seaports of New York, viz.: Philadelphia, Baltimore, Newport News, Norfolk, Wilmington, Charleston, Savannah, Brunswick, Jacksonville, Pensacola, Mobile, New Orleans, and Galveston are all competitive with New York and Boston for import trade. The southern ports named contend that, owing to various advantages enjoyed by New York, their business is dependent upon their ability to secure slightly lower inland rates than those to New York. This has long been admitted in practice by the railways, and differences have been made in their favor. Those who support the effort to secure a new law do so because they believe it would result in the prompt abolition of these differentials and so enable Boston and New York to secure a much greater share if not in fact to monopolize the export trade of the country. The principle of a fixed difference being now called into question after 26 years of more or less irregular use speaks volumes for the vitality of the arrangement.

Private Car Lines.—In reference to the agreements between railroad companies and the owners of private cars, it may be accepted as true that such agreements are in the main equitable, and favorable to the public so far as the peculiar circumstances of the case permit. The contentions which the private car lines are now making may have some justification. Perhaps being only indirectly engaged in interstate commerce they may not be subject to the law as it stands. That is a question for judicial determination. But there can be no reasonable doubt that it is within the power of Congress to say that these private car lines shall be regarded as engaged in interstate commerce and thus subjected to the statutes regulating such commerce. It cannot be admitted that private companies may be organized to carry on a regular system of transportation between the States, establishing what rates they please for the service and practising discriminations contrary to law, without being subject to any restraints or control or regulation. To concede that would be to give warrant for monopoly with the privilege of unrestricted abuses. The private car lines are unquestionably engaged in interstate commerce. The cars of these lines transport products between the States and the fact that they are leased to the railroads does not affect the character of their service.

Government Control.—Government control and operation are legally justifiable, if at all, under the commerce clause of the Constitution. But under judicial interpretation the power conferred by that clause is already so swollen as to dwarf almost every other national power. Its

RAILWAY TARIFFS

original purpose and scope were to prevent hostile commercial legislation by one State as against another and to make all the States but one country in their commercial relations with foreign nations. On this comparatively slight foundation has been built an edifice at sight of which, could it have been brought within their vision, the framers of the Constitution would have stood aghast and which would have doomed the Constitution to inevitable defeat. Under the present construction of the power, liberties and rights of contract once deemed inviolate are subordinated to its exercise and are not even protected by the constitutional amendments adopted for that express purpose. If Congress might lawfully do it, it certainly would be wise for that body to pause before making the experiment of endowing a commission with a jurisdiction which might well make it more powerful than the government itself. That the tendency in that direction would be strong admits of no question. To have even a semblance of competency the commission must have a reasonably permanent tenure of office. Its authority would grow with every year of its life, and before any long time would make its members the most important body of men in the country. No industry could afford not to be in touch with such commission, and every corporation, association, firm, or individual engaged in important commercial or manufacturing enterprise would be compelled to cater to it. In alliance with more or less of the great industries, it would be in a position to influence political conditions and to make itself strongly felt in the choice of Presidents and Congresses and Judges. See RAILWAY ECONOMICS.

The new construction projects now being launched borrow a peculiar, though it may prove an ephemeral, interest from the coincidence that now the academic controversy which has raged for two decades over government regulation of railroad freight rates has suddenly transformed itself into an acutely real legislative issue. The spectacle of railroad presidents dividing their busy hours between signing orders for the construction of main lines and dictating apprehensive protests against destruction by confiscation would be amusing if the subject were a less important one. Apparently the possibility of plenary rate-making power in the hands of a Federal tribunal gives none of them a trembling heart. The country wants rate regulation, but still more does it want new railroads, efficient railroads, and prosperous railroads. See AMERICAN STREET RAILWAYS; TRACTION, ELECTRIC; RAILWAYS, ELEVATED; RAILWAYS, HIGH SPEED; SUBWAYS, ETC.

EDWARD S. FARROW,
Consulting Railroad Engineer.

Railway Tariffs. The low cost of railway service as compared with other forms of land transportation constitutes the principal element in its superiority, and consequently the efficiency of this means of moving persons and property may be most simply and fully expressed in terms of railway tariff. The amount of the charge for any particular service is the product of a definite rate applicable between the points of origin and destination, or for the distance traversed, and to the commodity or class of passengers carried multiplied by the number of persons or the weight of the freight. Passenger and freight schedules showing the rates charged between all points reached and on all classes of traffic are published by every railway and large numbers of "joint" schedules are also necessary to inform the public as to the rates available over routes formed by two or more connecting railways. Rate schedules have been quite aptly defined as a device for getting back the very large aggregate expenditure necessary for producing this form of transportation in an enormous multitude of small and separate payments. Some appreciation of the truth of this can be obtained from railway statistics. The number of passengers carried by the steam railways of the United States during the 12 months which ended with 30 June 1902 was 649,878,505 and the number of tons of freight 1,200,315,787. The total service in carrying passengers was equivalent to moving 19,689,937,620 passengers one mile and the freight service to moving 157,289,370,053 tons of freight the same distance. The average charge exacted per passenger was 60 cents, or at an average rate of 19.86 mills per mile traversed while the average charge per ton of freight carried was \$1.03 or at an average rate of 7.57 mills per mile. The delicacy of adjustment attained is apparent when it is realized that a difference of one mill per passenger and per ton of freight per mile would have amounted to \$176,979,308 or 12.57 per cent more than the amount of all railway dividends paid during the year.

Passengers are classified for rate-making purposes according to the quantity of transportation which they purchase and the relation which their travel bears to the development of the territory and traffic tributary to the carrying line. Thus suburban passenger traffic is treated with especial liberality and accorded very low rates because populous and prosperous suburbs contribute profitably to both the passenger and the freight traffic of the lines along which they exist. Suburban passengers are also to be regarded as wholesale and permanent purchasers of transportation and are entitled to special consideration on that account. Similar reasons justify lower rates for commercial travelers and to persons seeking homes in newly opened terri-

RAILWAY TARIFFS

tory. The wholesale principle alone accounts for lower charges for parties of two or more, return trip tickets, and for especially long distances. It is also desirable to recognize the degree of elasticity, as to the volume of traffic supplied, of different groups of actual or potential patrons. Those who would not travel at all at the ordinary rates may be induced to travel in large numbers to conventions, etc., if quite low rates are made available for those purposes. Railways can often make these rates with profit to themselves and to their regular patrons provided they can do so without unduly interfering with their ordinary revenue. It is because the ticket-broker or "scalper" interferes with the effort to keep the different classes of travel separate, for rate-making purposes, that his existence renders railway officers reluctant to grant otherwise desirable concessions to special traffic. The profits of these dealers are really commissions for fraudulently transferring passengers from the classes in which they legitimately belong to other classes the members of which are entitled to lower rates; a practice whose possibility obviously tends to restrict the number of low rates offered to the public.

In general, regular, one-way passenger rates over any railway are proportional to the mileage traveled, although differences are made by great systems traversing regions widely varying in respect to density of population and other traffic conditions, and there is a natural tendency toward lowering the average per mile as the distance increases. Excursion rates, commutation, and other special tickets are usually, but not always, sold at rates based in some way upon the single one-way fares. It is commonly known that there has been a very notable and substantially continuous decline in American railway freight rates but the general belief is that there has been no similar movement in passenger rates. As a matter of fact the quality of passenger service is now much higher than it was 30 years ago and little if any real comparison is practicable among rates applying between the same points during different decades. It is worth noting that while passenger charges have either declined or remained stationary the cost of nearly every other incident of travel has advanced. Thus the rate for a single trip between Boston and New York is the same now as during the year in which the Astor House, then the finest hotel in America, was opened, but the standard rate per diem for room and meals at the Astor House was only \$2.50 or precisely the figure which is now the minimum price of a room alone at the first-class hotels of New York. Yet no one will deny that the difference in comfort between the hotel of 1848 and that of 1904 is far less than that which separates the passenger journey of the earlier from that of the later year. In 1848 a trip from New York to Philadelphia took five hours and cost \$4.00; it is now made in two hours and costs \$2.50. The rate from Philadelphia to Baltimore has decreased from \$3.00 to \$2.80 in the same period and the time from six hours to two. The table on the preceding page shows the average receipts in cents and decimals of a cent per passenger mile during the different years indicated for the United States and for several important railways, those for the years during which gold was at a premium having been reduced to their equivalents in gold.

The average in the foregoing for the United States in 1872 represents 44.16 per cent of the mileage then existing in this country, that for 1877 represents 66.77 per cent, that for 1882, 75.27 per cent, and that for 1887, 75.35 per cent. For later years substantially all the railway mileage of the country is represented. If the omitted mileage could be included for the earlier years, it would undoubtedly raise the averages materially.

Freight is also classified for rate-making purposes, although the commodities which move in the greatest volume like grain, coal, ore, cotton, lumber, etc., are usually excluded from the classifications applicable in the regions in which they move most freely and given "special commodity" rates. Owing to the stress of competition partly that among lines of railway connecting the same points of origin with the same destinations, but much more that among the many and often widely separated routes of transportation, water as well as rail, that are allied to different producing regions whose products find entrance to the same or competing markets freight rates are much less likely than passenger rates to be proportioned to the distances traversed or to conform to any arbitrary rule of adjustment. This is especially true of the rates on the great staple articles of commerce to which special commodity rates are commonly applied. For a great many years, however, there have been certain well-established rules of rate-making which have governed nearly all charges within the regions to which they are applied. Thus substantially all through traffic in the regions north of the Ohio and Potomac rivers and east of the Mississippi River, if it crosses, going either to the eastward or to the westward, a line beginning at Toronto and drawn southward through Buffalo, Erie, Pittsburg, Wheeling and Parkersburg to Huntington, W. Va., is charged for at rates derived from the contemporaneous rates on similar traffic shipped between New York and Chicago. This is attained by fixing certain arbitrary differentials which are to be added to or subtracted from the rates to or from New York if the business is destined to or comes from other important cities east of the Alleghany Mountains, by grouping the smaller towns and cities in this region with the larger ones at the same rates and by assigning certain percentages of the Chicago-New York rates to all stations west of the Alleghanies. Thus if the rate on grain from Chicago to New York is 20 cents per 100 pounds, the rate to Philadelphia will be two cents lower or 18 cents and that to Baltimore 17 cents. The same differentials would be used no matter how high or low the grain rate to New York might go. If it should be 25 cents the Philadelphia rate would be 23 and the Baltimore rate 22; if 15, Philadelphia would have a rate of 13 cents and Baltimore one of 12 cents. If a shipment originates at Indianapolis and is destined to New York the rate charged is 93 per cent of the rate which would have been applied had it originated at Chicago. On a shipment from Cincinnati to New York 87 per cent of the Chicago-New York rate is charged, on one from Cleveland, 71 per cent, on one from Detroit 78 per cent, on one from Peoria 110 per cent, and on one from East Saint Louis 116 per cent. Every railway station in this terri-

RAILWAY TARIFFS

tory has assigned to it a particular percentage. When business originating at a percentage point is destined to some other city, east of the western trunk line termini, than New York, the customary differential is applied to the proper percentage of the Chicago to New York rate. Nearly all rates on traffic to or from points west of the Mississippi River are made by adding to the rates to a point on the east bank of the river the percentage rates from thence to destination. Sometimes, however, the combinations are based upon Chicago or some other percentage point not on the river.

In the territory east of the Mississippi River and south of the Ohio and Potomac Rivers rates are generally made upon the "basing point" system. According to this system certain prominent cities, Atlanta, Augusta, Montgomery, Birmingham, Macon, and others are selected and given relatively low through rates. The carriers contend that these selections are not arbitrarily made, but that they are based upon the competition of rival transportation routes, and commercial conditions of controlling force. In making rates from or to points not designated as basing points the local rates from a basing point to the destination of the traffic are combined with those to the basing point. It is the practice invariably to allow the lowest possible combination on any basing point even though the traffic may not pass through that point. As an example of this method of rate-making the rates to Montgomery and Calhoun, Ala., may be cited. The rate from New York to Montgomery on articles classified as first-class in the Southern classification of freight is \$1.14 per 100 pounds, Montgomery being a basing point. The first-class rate from Montgomery to Calhoun is 26 cents per 100 weight and the rate from New York to Calhoun is the sum of these rates or \$1.40. The same system is commonly applied even though the destination is nearer the point of origin than the basing point but along a few lines the practice has been abandoned and the rates to the basing points made the maximum while in others the amounts added are arbitrary somewhat lower than the full local rates.

The classification of freight constitutes an important feature of rate-making. Three great classifications are in use throughout the country, while a few roads still maintain their own local classifications and a few state railway commissions impose their own ideas of classification upon the railway traffic over which they have jurisdiction. The Official Classification is applied to nearly all traffic, except that accorded special commodity rates, in the region generally described as east of Lake Michigan, Chicago, and the Mississippi River and north of the Ohio and Potomac rivers. The excepted traffic is that wholly within the State of Illinois where there is a classification promulgated and enforced by the State Railroad and Warehouse Commission and between certain points served by the Boston and Maine Railway. It is also applied to the local traffic of the Chesapeake and Ohio and the Norfolk and Western railways and to certain of the through business exchanged by these companies with their northern connections. The Southern Classification applies generally in the territory south of the Ohio and Potomac rivers and east of the Mississippi

River, but many of the railways in this region have their own classifications for local business and the States of North Carolina, Florida, and Georgia have imposed classifications made by legislative authority upon the local business within their several boundaries. The Western Classification applies west of Lake Michigan, Chicago, and the Mississippi River and to all classified traffic to and from the Pacific Coast. There is, however, a state commissioners' classification in Iowa and most of the traffic exchanged with the Pacific Coast is moved on special commodity rates. Each of these classifications has resulted from the consolidation of a large number of earlier classifications the separate existence of which formerly added greatly to the complexity of the railway rate situation in their respective territories. Further consolidation has been advocated and to the superficial view seems in the direction of simplicity, but those fairly cognizant of the diversity of the commercial and traffic conditions respectively governing in the three great divisions of the country covered by the separate classifications now in use are inclined to doubt the wisdom of attempting unduly to hasten the natural trend toward uniformity. The Official Classification has nominally six, but actually eight classes, the Southern has 15 and the Western 10. Each of these classifications provides different ratings for many of the commodities which it includes, according to whether they are shipped in car load quantities or in smaller volume and in all of them the same articles are often accorded different treatment when differently packed or otherwise prepared for shipment. The following table presents interesting data concerning these classifications.

| NAME OF CLASSIFICATION | Number of items in-cl'd | Items rated regardless of quantity shipped | | Items given different ratings for carload and less than carload shipments | | Items rated for carload shipments only | |
|------------------------|-------------------------|--|-------------------|---|-------------------|--|-------------------|
| | | Number | Per cent of total | Number | Per cent of total | Number | Per cent of total |
| Official | 9370 | 1722 | 18.37 | 7492 | 79.96 | 156 | 1.67 |
| Southern | 3664 | 1260 | 34.39 | 2332 | 63.65 | 72 | 1.96 |
| Western | 8044 | 2366 | 29.41 | 5336 | 66.34 | 342 | 4.25 |

Discriminations in favor of shipments in car load quantities are eminently just and proper as such shipments are much more economically handled than those in less than carload quantities and their increase means the more effective utilization of the transportation facilities which are available. That there is a tendency toward increasing the number of these discriminations may be seen from the following statement which show the number of items in each classification and the numbers with regard to which such differences were made, for the years 1887 and 1902.

It should be understood that the increase in the number of items classified does not so much indicate an increasing complexity and diversifi-

cation of freight traffic, although it represents some growth in that direction, as it does a more complete recognition of the importance to the carriers, and through them to the public, of securing those forms of preparation for shipment which are most convenient in handling. Proper preparation is encouraged by discriminations in the classification which accord more favorable ratings to the same articles when they are packed in the most convenient form than when less desirably prepared.

Freight rates in the United States have shown a decided and continuous downward tendency and even during the recent years of high prices and corresponding decline in the value of the medium in which charges are paid there has been but little interruption of this tendency. The most important of all changes are those affecting the rates between New York and Chicago because of their use as the basis of other rates, which has been explained, and their relation to the export trade of the country. The following statement shows comparisons between the average rates, in cents per 100 pounds, collected on shipments of the articles named from Chicago to New York in 1867 and in 1902:

* In gold.

RAILWAY TRAFFIC

for the later years. If the averages of the earlier years could be made to represent all the mileage of those years, they would be higher.

H. T. NEWCOMB,
Author of 'Railway Economics.'

Railway Traffic. The amount of traffic that can be handled over a railroad has been greatly increased by the use of the telegraph and telephone for dispatching trains, by the adoption of electric and other highly improved signals, and by the possibility of running both passenger and freight trains at higher speeds as the result of having more powerful locomotives and power-brakes operated from the engines. The vast improvements in travel and traffic have resulted quite as much from the progressive adoption of the vehicle to the service to be performed, as from betterments in the road-bed and locomotive.

No matter what the resources of a country may be, the transportation problem is always vital, because without proper transportation facilities markets cannot be made or maintained. The buyer is always anxious for the early receipts of his freights, and countries prosper in proportion to the time saved on freights transported, because time saved means a reduction in expense in the interest account. The railroad must accept lading when accompanied by proper billing instructions, and by law is obligated to transport it in a reasonable manner, giving reasonable service between initial point and final destination, said service to be in accord with the contract, it being additionally recognized that every allowance made in the freight rate is an allowance made in the obligation of the railroad for service, and that reasonable service cannot be rated the same on commodity freights as it is on freights of the higher classes. The entire organization of a railroad is to the end of the movement of the individual car, and every expense is in relation to the earning capacity of the car.

Sources of Revenue.—Steam railroads derive their principal source of revenue from hauling freight. In 1905 the receipts of the Pennsylvania Railroad Company from freight traffic were \$100,093,828, while the receipts from passenger traffic were but \$27,392,393. This result was accomplished although the gross receipts for hauling the average freight train for a mile were \$2,996 at a cost of \$2.11, making the net profit about 88 cents. In view of the tendency now to electrify railroads in order that the passenger traffic may be handled with greater speed, with more frequent service of cars and possibly with more safety, and the tendency also in some States to cause a reduction in passenger fares, it becomes a question whether in a few years the passenger business will not be entirely separated from that of carrying freight, at least so far as it may be divorced without endangering charter rights.

Cars.—The use of private cars at the present time may be divided into two general classes, those in which the property of the owner of the cars is transported, and those in case of which the owner is not interested in the contents of the car. In the first case the shipper owns the car, and the car is ordinarily only used for the carriage of the property of the owner. In the second class the cars are usually owned by some

private car company, which constructs or purchases the car, keeps it in repair, and leases it to the railroad company. The use of the private car originated in the necessity for special equipment to serve a particular purpose. Live stock, for example, is transported over long distances. In the course of such transportation the animal shrinks in weight and deteriorates in selling quality, besides suffering from want of water, and from crowding and trampling. Hence, the dictates of both interest and humanity require that the animal should be transported as comfortably as possible. And this has led to many attempts to devise a car in which stock could be fed, watered, and carried without injury. When the inventor of such a car has in the past approached the railroad manager with his invention, he has generally been informed that the railroad had no money with which to experiment, but that if this car when constructed and ready for use would fulfill his representations the railroad would be glad to hire it for a fair rental. This has brought about the organization of a number of companies for the construction and operation of stock cars. The same thing has been true of the refrigerator car. When the necessity for such a car first became evident, various designs were brought forward. Here again railroad managers were reluctant to invest their money in what was largely in the nature of an experiment. The result was that these cars came to be constructed by private companies, which leased the cars to the railroads in the same manner that the stock cars were provided.

Prior to the advent of the steel car, the greatest maximum capacity of a car occupying 30 feet of track was 60,000 pounds, and the weight of this car was approximately 40,000 pounds, so the percentage of live load to dead weight was as $1\frac{1}{2}$ to 1, or of the total weight of a train 60 per cent. was paying load and 40 per cent. dead weight. With the steel car it is possible to load 100,000 pounds, or 50 tons, on a car weighing 38,000 pounds, or 19 tons, which increases the proportion of paying load to dead weight to $2\frac{1}{2}$ to 1, or to approximately 75 per cent. of total weight. Nor is the increase in percentage of weight per car the only benefit derived from the increased capacity. The 50-ton car occupies no more space upon the track than the 30-ton car, so the actual capacity of sidings and track room is almost double. Naturally, an increase in weight of rails and increase in hauling capacity of locomotives follows the increased tonnage capacity of the cars. The train load is increased not only by increasing the capacity of the cars, but by diminishing the number of empty cars hauled and by endeavoring to load all cars to their full capacity.

The large capacity car, both coal and box, reduce the cost of operation if properly handled, but so long as light, bulky commodities are shipped, just so long will there be a difference in drawbar-pull on light and heavy cars to contend with even when all cars are of uniform large capacity, and the method of basing on average performance will be as far as ever from securing the proper results, and so long as trains will be made up with light loads at the head end, and heavy loads at the rear, no average plan can make provision for drawbar-pull in such cases, and no proper adjustment can be made

RAILWAY TRAFFIC

unless this factor is taken into consideration. The matter of adjusting the drawbar-pull of each gross of car at each individual location in a train is made feasible and practicable by the aid of a mechanical device, hence it is not a theory but a condition that must be met, and one that the mechanical and operating departments must join hands in overcoming.

At the present time there is a noticeable tendency toward uniformity in couplers and uncoupling attachments and an increase in their strength. The different makes of couplers used are steadily decreasing in number, the new cars turned out being equipped with one or another of four or five standard makes. These new couplers are generally stronger than the old ones, and this improvement in the strength of couplers has reduced the number of defects. Grab irons are receiving much better attention than formerly and it is now the exception to find cars unequipped with these important safety devices. Loose and bent grab irons are much less frequently found in service, and the practice of using uncoupling levers in lieu of grab irons is also being discontinued.

Operating Expenses.—From the close of the American Civil War to the present time, industrial changes have been more rapid in the United States than anywhere else in the world. Within this period the railway system has grown from 35,000 miles to 217,000 miles; population has more than doubled; wealth has increased more than fourfold; populous cities and sovereign States have grown up where at the beginning was nothing but wilderness. Progress of similar character is going on to-day with undiminished activity. Railways have met this progress by constant adjustments of and reductions in the charges for their services. In 1899 it cost \$856,968,999 to operate the railways of the United States; in 1903 the same expenses amounted to \$1,257,538,862, an increase of \$400,569,863. In 1899 railway labor, exclusive of salaried employees, received \$481,264,109; in 1903 the same classes of labor received \$720,580,923, an increase of \$239,316,814. In 1899 the fuel used by locomotives cost \$77,187,344; in 1903 it cost \$146,509,031, an increase of \$69,321,687. Comparing operating expenses with work done, it appears that in 1899 for every dollar expended for operation the railways were able to carry 17 passengers and 165 tons of freight one mile. In 1903 the passenger mileage for each dollar expended in operation amounted to 16.6 and the freight mileage to 138. Each \$1 of operating expenses in 1899 brought in \$1.53 in revenue, not including that from miscellaneous services, while each dollar of operating expenses in 1903 brought in only \$1.38 in revenue.

Low Rates.—The low rates made by American railroads are the surprise and wonder of foreign railroad men, averaging not more than one-third to one-half of the rates for similar services in other countries under government control and ownership. The foreign railroad officials who have studied this subject here credit these low rates to the sharp, intense competition between railroads having individual liberty of action and desire to build up new territories, forcing the managers and heads of departments to an intensity of research, investigation, and development of economies in cost of service unheard of in countries where the rail-

roads are owned or controlled by the government.

Passenger Service.—The service of transporting passengers differs in many particulars from the freight service. Goods are shipped, while passengers travel of their own volition, controlling the time and direction of their movements. One important difference between these branches of the service is that most freight is moved in carloads or trainloads, the start being made when the car or train is loaded, while the passenger business is performed by trains that run on fixed schedules. Some commodities, like milk and fruit, are despatched by trains which run strictly according to schedule, and the collection and distribution of the traffic at the local centres of production or consumption are usually accomplished by *way-freight* trains which have a definite time of arrival and departure. Whether viewed from the standpoint of public benefit or considered with regard to the volume of business done, and profits received by the company, the transportation of freight is the most important service performed by the railroad. As an illustration, showing the percentage of freight earnings, the gross earnings of American railways for the year ending 30th June 1905 were \$2,073,177,325. This total comprised earnings from the passenger service amounting to \$572,109,366, or 27.60 per cent.; earnings from the freight service amounting to \$1,491,827,020, or 69.90 per cent. and other miscellaneous earnings amounting to \$51,885,257, or 2.50 per cent.

The passenger service, to a far greater degree than is required in the freight business, must provide for speed, safety, comfort, and convenience. The development of the Pennsylvania Limited is typical of the strides which have taken place with regard to long distance passenger traffic. When first established it left New York 7.55 A.M. and arrived Chicago 9.40 A.M., making the run in 26 hours, 45 minutes. It now leaves New York 10.55 A.M. and arrives Chicago 8.55 A.M., making the run in 22 hours, 50 minutes. Returning, it leaves Chicago 5.30 P.M., making the run in 23 hours. Changes in service accompanied improvements in speed. The Pennsylvania Limited is famous as the first train in the world to afford all the comforts of the home and conveniences of the club. It was also the first train to be vestibuled from end to end. In addition to a high-grade equipment, built especially for this train by the Pullman Company, the train makes special features of its stock quotation service, the barber, bathroom, stenographer, and ladies' maid, which it was the first to provide for the convenience and comfort of patrons.

The service of the Twentieth Century Limited, which is the eighteen-hour train of the New York Central Lines between New York and Chicago, was inaugurated 15 June 1902. Its superior equipment and the splendid physical condition of the roadbed and tracks over which it glides enable its fast time to be made with perfect ease and comfort. During the Columbian Exposition at Chicago in 1893 the New York Central Lines inaugurated the first 20-hour service between Chicago and New York, and from May to November in that year the "Exposition Flyer" maintained its schedule with great exactness. In 1902 the management of

RAILWAY TRAIN DISPATCHING AND TRAIN HANDLING

this great system of roads, recognizing the nature of the demand for fast service between the two leading commercial centres of the country, evolved the Twentieth Century Limited, which maintained the 20-hour schedule every day in the year. The great success of this train has made it world-famous. Its ability to furnish stenographer, telephone, and telegraph facilities, enabling the transaction of business on the journey, has made it very popular. In response to the numerous demands from its patrons the running time was reduced two hours in June, 1905, making its daily journey of 963 miles in 18 hours, a remarkable achievement. This is a greater number of miles at a higher speed than is run by any other train in the world.

Growth.—The growth of the present railway system of the United States has been little short of marvellous. It was not until 1835 that it reached as much as 1,000 miles, being 1,098 miles in that year. Note the growth since then:

| | |
|------------|---------|
| 1850 | 9,021 |
| 1860 | 30,026 |
| 1865 | 35,085 |
| 1875 | 70,096 |
| 1885 | 128,320 |
| 1895 | 181,115 |
| 1905 | 217,328 |

There are two very striking facts to note here: First, that in spite of the Civil War, 5,059 miles of railway were built during that unhappy period; second, that in the 70 years following, our railway mileage was doubled.

During the latest year for which statistics are available, the railways of the United States carried, as compared with 1885:

| | 1885. | 1904. |
|---------------------|-------------|---------------|
| Freight, tons | 437,000,000 | 1,300,000,000 |
| Passengers | 351,000,000 | 720,000,000 |

Reckoning our population at 80,000,000 in 1904, it is as if every man, woman, and child in the country made nine steam railway trips during the course of that year, and also moved 16¼ pounds of freight.

The reduction since 1865 of railway freight rates in the United States is also remarkable, as illustrated by the fact that wheat by lake and rail has fallen from 29 cents to 5 cents; by railway only from 46 cents to 11 cents.

HUGH T. DOWNING,
Mechanical Engineer, New York.

Railway Train Dispatching and Train Handling. The dispatching and handling of trains successfully to meet the demand upon railroads in handling a through passenger service, suburban traffic, freight traffic, U. S. mail, to obtain traffic against competition, and moving such traffic cheaply, promptly, and safely, is an important field of railway operation, and makes great demands upon the operating official.

The engineering department has performed its part in building bridges, laying heavier rail, making stronger track and better roadbed, in stalling interlocking plants and block signaling, and providing for heavy engines.

The mechanical department has met the re-

quirements in designing large engines of greater power, enabling heavier trains to be handled at greater speed. It would thus seem that the engineering and mechanical departments have reached the limit of their expansion on the lines mentioned. See RAILWAY CONSTRUCTION; RAILWAY HEAVY FREIGHT TRAINS; RAILWAY TRAFFIC.

This brings the situation to the operating official, putting in his hands the opportunity and responsibility of getting the very best results from the facilities and equipment at his command. The handling of through passenger trains requires that the trains should have assigned an engine capable of making the schedule with 20 per cent reserve power, thus being able to overcome unexpected delays. As few stops as possible should be scheduled for such trains. If traffic is sufficient, at intermediate points a local train should be run ahead of the through train to carry passengers to a point where these stops are made so passengers can have the opportunity of taking the through trains. Express and mail should be handled on through locals and mail trains provided for such service. If the scheduled trains should at times require more cars than the regular assigned train, instead of adding cars another engine should be provided, or better still, run a second section, loading the first section with all passengers to final destination of train of the initial road, and have the second section do the local work, not letting the first detain the second, thus saving delay also to first section. The public in the territory the through train covers is entitled to have the train on time. This can be accomplished not by sacrificing train schedule to connections, but if necessary by running the train from initial point on time for the passengers on the road served and a second train for the connection. This is not now generally the practice, but the time is quickly coming when this will have to be done by many more roads. Many through trains, specially on single-track roads, are badly detained by the issuing of too many train orders, sometimes giving an engineman eight or ten orders at a station. For enginemen and conductors to understand these orders 12 minutes or more is consumed, and the engineman is handicapped because he is fearful of overlooking an order. If the train is not overloaded and ample power has been provided, it would be much better, if the train is not to exceed 30 minutes late, to give no restrictions by placing orders in favor of freight trains. The engineman would be freer to devote his time to making a good run, and would most likely make up time, and the general movement of the freight trains would be better. The passenger trains should be kept on time and the freight trains will make good runs if they have the proper power and are not overloaded, getting out of stations promptly, and taking advantage of every minute. Freight train employees should be educated to the necessity of giving passenger trains the proper clearance, and that in stormy or foggy weather they cannot make as good a run ahead of or against passenger trains. If they will observe these conditions they will keep out of the way, not only preventing delays but avoiding the possibility of not properly protecting their train. Short time on passenger trains, especially on a road without block signals, has caused serious head-on

RAILWAY TRAIN DISPATCHING AND TRAIN HANDLING

and rear-end collisions. When excursion trains are run they should be handled with the same promptness, not given any more cars than can be well handled and make a good run, because usually a large number of passengers are taken on at stations. With a long train there is greater delay, passengers are more liable to injury, and the train is in danger. A cheap passenger rate sometimes leads to the handling of too many people at the risk of accident; better run more trains with less cars or not give excursion rates at all. Women and children are generally handled on such trains, thus making the risk greater. Some of the most serious accidents on American railroads have been to excursion trains; sometimes because they are run as sections of a regular train that has not had sections run, and sometimes because the trains were too long and the power furnished poor. The number of trainmen should be increased on excursion trains.

Suburban Trains.—The movement of population in the large cities is constantly toward the towns and villages situated on railroads adjacent thereto. The public consult timetables of different roads, and conclude to locate in such suburban places because the train schedule enables them to go to their business and return home at a certain time. They expect to use certain trains. This being the case timetables should not be changed, otherwise the public will be greatly discommoded unless given other service that will answer their purpose or improve the conditions. Most suburban roads have suburban territory covering zones of 7, 13, 20, and 30 miles. Where a road runs 200 or more trains per day and carries 50,000 passengers per day (as a rule the greatest percentage is handled from 7 to 9 A.M., 5 to 7 P.M.), three or four tracks should be provided, two for express and two for local trains. Usually 70 to 80 per cent of the passengers carried are in the 13-mile zone. As the heavy movement in the morning is toward the city, yards and engine-houses should be provided to hold a large number of coaches and engines at the 13 and 30-mile zones. Small yard and turntable should be provided at the 20-mile zone, where engines can be turned, saving the running of trains a greater distance than the requirements. Where only two tracks are provided the entire distance, and a third track provided three or four miles long (between zones 20 and 13), trains should be run leaving all zones early enough for the early workers; trains leaving 30-mile zone making all stops up to the 20-mile zone, and then express trains from there, or making alternate stops at a few points between zone 20 and destination. Trains should be started from zone 20 making all stops to zone 13, and express from there, or making only two or three alternate stops from zone 13 to destination.

The percentage of passengers moved between zones 13 and 30 being smaller, to save hauling cars not needed beyond zone 13, a coach track should be provided, connected with steam heat in winter, and trains that have left zones 30 and 20 requiring more coaches to pick up passengers where they make stops between zone 13 and destination can do so. The greater movement being from zone 13, instead of having all trains leaving zone 13 make all stops, have first train

out make second station stops and next train first station stops, alternating stops from zone 13 to destination; or jump three or four stations into destination. This arrangement to be carried out during the rush hours, thus shortening the time and running semi-express trains.

By having the third track, trains can be started from zone 13 toward destination, and held at end of third track, thus running express trains around the local trains. Trains may have to be scheduled from zone 13, following express trains that make no stops from zone 13 to destination. While a branch road may branch off, say at zone 20, a few through trains should be run solid on the branch where business will warrant it. When trains are not run through on branch, cars should be attached to trains going to zones 20 or 30, and an engine attached at zone 20, thus saving transfer of passengers or baggage. As many people besides passengers going to their business have baggage it is necessary that a combination baggage car should be provided for each train. Express business should not be handled in the rush hours, except in solid carloads, requiring no work where trains stop. An occasional count should be made of the number of passengers that get on at each station; this will show if the trains as scheduled for stops are serving the people properly. The movement of passengers going to the city may then be controlled, because they come to the trains that are scheduled to stop. A schedule to suit all may not be made, but if the greatest number are taken care of satisfactorily that seems to be the fair way of concluding the service is right.

The roads located in New Jersey that have to make connection with boats have harder conditions to meet than if the destination of the passengers ended on the Jersey shore. Two and three trains are scheduled for a boat; this being the case the boats are scheduled for certain trains and the train schedule must be made or passengers will not reach their destination on time.

The movement of passengers from city to home is more complicated to handle than the movement coming in, because the number of passengers for any train is unknown, when you are hauling heavy trains. This can be overcome usually by having extra cars set on rear of train at starting point, kept locked and used only when necessary. When you have reached the limit of the number of cars you can handle in a train two or three trains can be scheduled same leaving time, scheduling first train to make first stop, 20 miles out, and all stops between zones 20 and 30. Second train making first stop 10 miles out and local stops to 13-mile zone. Third train first stop 7 miles out and all stops from there to 13-mile zone. This keeps the trains separated. Where four trains are run on same schedule, first train goes to 20-mile zone and the three trains following alternate stops to destination so that they are kept out of each other's way. A record of this movement should be made occasionally showing where the passengers get off, and this will show how well the public are being served in the homeward movement.

The locomotives used in suburban service should be the very best, and have at least 20 per cent reserve power. Where trains are mak-

ing several stops, handling coaches 65 and 70 feet over all, seven cars should be the limit. Ten cars might be handled in express, making a run of 20 miles without a stop; eight cars is better.

As the traffic becomes dense between zone 13 and city, this condition forces more trains from zone 13, and interferes with train movement from zones 20 and 30. To increase handling of passengers at an increased rate the territory from zones 30 and 20 should be handled by having four tracks, so that express trains can be run from zones 30 and 20 without making any intermediate stops between zone 20 and destination, making much quicker time, bringing the population nearer the city, and giving the public an opportunity of obtaining homes at nearby points, thus increasing the passenger haul and increasing earnings with same number of trains run from zones 30 and 20.

Freight traffic gains in proportion with the increase of passengers hauled. With the coming of trolley competition, the day seems to be not far away, wherever travel is dense, when the ideal timetable will schedule trains leaving initial points at 5, 10, or 15 minute intervals in the rush hours to zones 20 and 30, 3 and 5 minute headway to zones 7 and 13, and 20, 25, and 30 minute headway at other hours of the day to the 30-mile zone increasing the number of trains run as the traffic demands, virtually giving trolley or subway service.

Freight Train Handling. The handling of freight traffic has become a great factor in the railroad business and greatly affects the commercial world. The merchandise movement demands and obtains a regular schedule between our great cities and the Pacific coast. The Pacific is forwarding to the Atlantic fruits that require quick and regular movement. Dressed beef and live stock from the west to the Pacific and to the Atlantic is handled and landed at destination for domestic use and export with precise schedule. The manufacturer, builder, merchant, in fact all mercantile life depends upon the promptness of the handling of traffic, not only for the promotion of trade, but to get the best use of capital invested. Not only is quick traffic to and from the far west necessary, but also to the local points which the road may be serving. The through trains should be built up with cars destined to the points of the connecting line and points beyond, and sufficient trains run to accomplish this. No switching should be required at any intermediate point, changing engines at division points should only be necessary. Another train should run to move the merchandise to the local territory, arriving at destination by 7.00 A. M., serving a territory of 300 miles. A second train should be run serving a territory 400 miles out for second morning delivery. There should be a special train for the movement of coarse freight to the 400-mile point with cars for intermediate points, thus insuring the freight going through without being set out and delayed. If the freight at initial point is not received in time to go out on the day it is loaded, better time is made by holding it over until the next day than by sending it forward in extra trains. The handling of less than carload freight from the great cities has become so heavy that the merchant located 70 or 80 miles out buys with

the expectation of getting his freight the next morning. This is done by loading straight cars of less than carload freight for the different towns and villages, running pickup trains to move these cars to destination, and setting the car at freight house ready for delivery to consignee. This has other merits than making schedule time, it saves handling the freight, damage or loss. It also does away with many way freights, and those runs handling car lots and picking up small lots. The car equipment represents a large amount of capital invested, and the number of miles made by a car represents its earning power, it is therefore imperative that the empty cars be moved quickly to point where load can be obtained. This being the case a system is necessary in the building up of trains of empty cars, and this should be accomplished with trains going to the farthest point to save delay in transit. The kind of cars which are in most demand should be sent forward in solid trains, not only to insure prompt movement of trains, but to prevent road power being delayed doing switching. Where passenger train movement is frequent, freight trains running extra should not be started from a terminal too little distance ahead of passenger trains, but should follow them and save delay to power lying on siding, and avoid tiring out the train employees. The cars in way freight and pickup trains should be built up in station order. Where many industries are located and freight traffic locally is heavy, roustabout drills had better be worked covering certain territory, doing the switching for warehouses, team tracks and industries, lining up cars for pickup trains. Roustabout drill engines, when through for the day, can take cars to same yard they started from to be lined up for certain trains.

The telephone is a great auxiliary in the handling of trains if properly used. Locating telephones at blind sidings, at ends of long passing tracks, making communication between conductor and telegraph office, connecting up towers with telephone system so operators can be advised and trains dispatched through instruction from dispatcher to towerman, etc., are all means of saving valuable time and getting desirable results.

We have explained what seems to be the best system in lining up train service, where good power and facilities are furnished. We may have all these things, but if the proper attention is not given to following up the movement of trains the best results will not follow. The train dispatcher must keep in close touch with the situation, doing his part to see that a clear track is given to clear fast trains, watching closely the movement of the trains moving in suburban service. Where these trains are running on a close headway if a train should be disabled he must quickly and intelligently grasp the situation by arranging for the handling of the passengers in other trains. In other words, change the schedule to meet conditions. Fast freight trains can be aided by train dispatchers keeping inferior class trains advised where to side track. Complete system of reports are necessary, advising of all delays, and these reports must be carefully looked after, following every delay, bringing to the attention of the different departments, or to the employee at fault, their shortcomings, bearing in mind

RAILWAY TRAIN LIGHTING

that as eternal vigilance is the price of liberty, so eternal vigilance is necessary on the part of the operating officer who expects to get good results.

C. H. KETCHAM,
Superintendent Lackawanna Railroad.

Railway Train Lighting. The expression, "train lighting system," as distinguished from "car lighting system," has come to be used to designate the various electrical systems for lighting steam railway trains. There is, perhaps, no good reason for the distinction, as the greater number of electrical systems are applied to single cars as units. The inventors of the newer methods seem to have had in mind the fact that steam operated trains, not electrically operated cars, were to be lighted. The steam train consists of a number of dependent parts, all going to make a unit. The electric train generally is made up of a number of units, each of which can be operated alone.

FIG. 1.—Method of driving the dynamo, Sperry-Lyndon train lighting system.

History.—In the early days of railways, candles played an important part in the lighting of the cars. This method was soon replaced by lamps burning various kinds of oil, kerosene being the only one whose use has persisted to the present day. About 1884 the need for better lighting of trains caused a number of railway companies and others to take up the study of the problem presented. As a result two distinctive systems came into use. In one compressed gas stored in tanks under the car is the illuminant. In the other so-called "air gas" is formed by forcing air through a carburetter containing naphtha, or a light hydrocarbon oil and the resulting gas is burned in suitable lamps. One system, belonging to the former class, made use of compressed illuminating gas, such as is used for city and house lighting, but this was not successful on account of the poorer illuminating quality of the gas as compared with oil or air gas.

Pintsch System.—The oil gas system, better known perhaps as the Pintsch system, uses an oil distilled from crude petroleum in suitable retorts. The gas after leaving the retorts is cleaned and compressed and stored in reservoirs, ready for charging the car tanks. Pipes leading from the reservoirs conduct the gas to the train shed and, by means of flexible hose, it

is passed into the car tanks. These usually hold several days' supply. The car equipment, in addition to the tanks, consists of a regulating valve for reducing the pressure to a point suitable for the burners, distributing pipes and regenerative burners, that is, burners which heat the gas before burning it, a treatment which increases its illuminating power.

Frost System.—The air-gas system, a type of which is the Frost system, came into use about the same time as the oil gas. In this the carburetter, a tank packed with some absorbent material such as asbestos wicking, is filled with naphtha or gasoline, and air, from the compressed air tanks connected with the air-brake system, is passed through. A reducing valve lowers the pressure to a point suitable for burning. In its passage through the carburetters, the air takes up the hydrocarbon vapor. The mixture is then led to the burner, passing through a heating coil on the way. This coil is placed above the burner and is heated by the latter.

Electricity.—A number of objections have been urged against all such systems of lighting cars. At times a disagreeable odor is given off. The lights can not easily be subdivided and placed so as to get the most effective distribution of light; the lighting is generally accomplished by means of several burners or groups of burners placed along the centre aisle of the car. Any system depending upon a highly inflammable material is a possible source of danger from fire. This is particularly true in case of accidents, the very time when it is most difficult to get away from the danger. Naturally, therefore, railway engineers turned to the electric incandescent system, as it is not only entirely free from all fire risks, but possesses a number of

FIG. 2.—Transmitting mechanism, Sperry-Lyndon train lighting system.

distinct advantages over oil or gas systems. Thus, many small lamps may be arranged so as to give the best results, throwing the light just where it is needed. Compare the usual equipment of 80 incandescent lamps in a Pullman with the 6 or 8 gas lamps usually thought sufficient. The electric lamp gives a soft, white, steady light. There is no odor and no vitiation of the air. On the other hand, it has not been easy to adapt the incandescent electric lighting system to steam railway conditions. One of the first requirements is that the voltage at the lamps must be maintained constant and steady. Another is that the system must call for little attention from the train hands. It is also

highly desirable that the cars be independent, so that they may be detached from the train without putting out the lights. In the first attempts to use the incandescent system on railway trains, storage batteries were placed on each car. A number of roads tried this, but the results were not entirely satisfactory, for while the advantages of the incandescent system were obtained, a number of serious disadvantages developed. The voltage of a storage battery varies considerably from full charge to discharge. Hence regulating lamp resistances were required. These were usually operated by hand. Cars equipped in this way could only run over routes where suitable charging facilities were to be had, and it was found that those responsible for charging the batteries often did not know the proper method of procedure, with the result that the cells deteriorated rapidly. Moreover, charging takes time, as a storage battery can not be filled up as one would fill a gas tank. The car was therefore laid up for several hours every day or two for charging. Some of these objections are not serious under certain conditions,

FIG. 3.—The complete system.

such, for instance, as that of a train which always runs over the same route and lies in the train yard several hours at the end of the run, but it is obvious that the storage battery system lacks flexibility and is not adaptable to all conditions of service, and it now seems to be only a question of time when all passenger cars will be lighted electrically.

The next advance in train lighting consisted in placing a small generating set in the baggage car. Steam was supplied from the locomotive, though an oil engine might be used. Wires were run throughout the train for the lights, and in addition, each car carried a small storage battery to supply the lights should a car be detached temporarily from the train. This system has given good service on certain through trains, but it is not flexible, as the train is the unit, not the cars, and there is some objection to putting the generating plant in the baggage car where it not only takes up space, but requires attention. While better than the simple storage battery equipment, because the batteries can be cared for properly and an improved service can be given, it does not meet the requirements for a completely automatic single car equipment.

Axle-light System.—This requirement for a completely automatic car equipment is met by the so-called "axle-light" systems. In general, these consist of (1) a small dynamo mounted on the car truck and driven by any means from the car axle. (2) a small storage battery to care for the lights while the dynamo is not in service,

(3) the usual wiring and lamps, and (4) several automatic devices for charging the battery and maintaining the voltage constant. The usual equipment for a Pullman car consists of a dynamo capable of delivering two and a half kilowatts at the lowest speed, at which it becomes operative, about 80 25-watt incandescent lamps, and a storage battery capable of running the lamps during any ordinary stop. There are a number of systems belonging to this class which have been patented. Certain of them are now (1904) on trial on various roads. The requirements of such a system are: The voltage across the lamps must be constant at all times. The batteries must be kept fully charged and all governing must be done automatically. The axle-light systems differ from each other in the method of controlling the voltage of the dynamo. Assuming the latter to be excited from the storage battery, the strength of the magnetic field will be practically constant, and hence the voltage, unless regulated, will vary directly with the speed of the car. The usual limits within which the dynamo must operate are 14 and 80 miles an hour. Fast trains not infrequently attain speeds of over 70 miles an hour for short times. Below 14 miles an hour the dynamo is cut out of service. The range, however, is nearly six times the lower speed. The methods of governing may be divided into two groups. Those in which the speed ratio of car axle to dynamo armature is kept constant, and those in which the speed of the dynamo is kept constant, independent of the car speed.

Taking up the former class, the dynamo may be driven by a belt, by gears or by a sprocket chain. If the first device is adopted, it is usual to swing the dynamo from the truck and provide a belt-tightening arrangement. Gears and sprocket chains should run in oil. The general operation of these systems starting with car at rest is about as follows: The lights are maintained by the battery until the minimum operating speed has been reached. At that point the voltage across the dynamo has risen to a higher point than that of the battery, and a switch actuated by a solenoid connected across the dynamo, closes the dynamo circuit. The dynamo then takes up the load, supplying the lights and charging the batteries. As the speed changes the dynamo excitation is changed in the opposite sense by an automatic device which may consist of a little motor-driven exciter or a field rheostat actuated by a solenoid, or any other mechanism which will serve the purpose. As the batteries become fully charged their voltage rises and they take less charging current. Since the dynamo must give a voltage higher than that of the batteries, its voltage is too high for the lamps and must be lowered by a resistance in the lamp circuit. This is variable and may be controlled automatically so as to care for all conditions of load. It also serves to regulate the voltage at the lamps during the discharge of the batteries. As the car must be able to run in either direction, the dynamo connections must be reversed with a change in direction of motion in order that it may be connected properly to the battery. This may be accomplished by a pole-changing device operated by the dynamo axle, which throws a switch one way or the other according to the direction of rotation.

RAILWAY TRANSPORTATION

A simpler plan is to mount the brush-holder so that it may be shifted easily and to allow the friction of the brushes on the commutator to shift them through a suitable angle so as to keep one brush always positive.

In the second type of axle-light system the speed of the dynamo is maintained nearly constant by a variable speed drive. In one of the early systems of this type the change in driving rate was effected by allowing the belt to slip. In a later type a variable friction drive controlled by the voltage of the system changes the ratio so as to maintain the proper charging current for the batteries. In a well worked out system of this type, recently described, the work of operating the driving mechanism and the lamp resistance is performed by oil maintained under pressure by a small motor and controlled by a compound wound solenoid. In this system

FIG. 4.—Solenoid and Auxiliary Switch, Sperry-Lyndon train lighting system.

the proper rate of battery charging is maintained, the dynamo goes out of service when the batteries are fully charged and no other work is being done and also should the speed of the car exceed 80 miles an hour. In systems belonging to this class a small high speed dynamo may be used, as its speed is nearly constant.

Axle-light systems should be entirely automatic and very durable. They are not likely to get much attention and that not of the best. They must be entirely reliable. Such systems are more costly to install than the gas systems, but they are far superior in the results obtained. Although the power required for operation is furnished by the locomotive it is comparatively small and is certainly less than that due to variation in the train resistance due, say, to a slight change in the lubricating oil. Some such system of train lighting will doubtless be adopted largely in the future, at least until the electrically operated train replaces the steam locomotive.

WM. HAND BROWNE, JR.,
Editor *The Electrical Review.*

Railway Transportation. Railway transportation is concerned with the movement of persons and things. To accomplish this movement the railway companies have organized and developed their passenger, freight, mail, and express services. In carrying passengers and freight by rail the railway corporations supply the entire agency, but in the mail and express services they co-operate with the government and

the express companies for whom the railway companies act as carriers. Formerly, the through freight service was to a large extent carried on jointly by the railway companies and corporations called fast freight lines or despatch companies, much as the express business is now conducted; but the work of the auxiliary freight companies has been mostly taken over by the railway organization.

The Freight Service.—The transportation of freight is the most important service performed by the railways. The earnings derived from carrying freight are between three and four times the receipts from the passenger traffic. The dependence of society upon the cheap and unrestricted movements of commodities is much greater than upon rapid and inexpensive travel; because the extent of nearly all forms of industry is definitely circumscribed as regards materials and markets, by the length of the radii of economical transportation of commodities. To travel with comfort and speed is highly convenient, to ship freight long distances with economy and expedition is essential to modern business life.

During the year ending 30 June 1902 the railway companies in the United States reported a total tonnage of 1,200,315,787 tons. This is, however, double the amount of freight actually turned over to the railways by shippers, because much traffic is handled by two or more companies and is reported by each carrier. The tonnage actually received from shippers was 581,822,441. The average distance which each ton was moved was 268 miles; hence the number of tons carried one mile—the ton mileage—was 157,289,370,053. Over half of this enormous traffic, 52.36 per cent, consists of coal, iron ore, and other minerals. Manufactures make up somewhat more than one seventh of the tonnage; forest products furnish one ninth, and agricultural productions nearly one tenth. The remainder of the traffic, about one eighth of the total, comprises animal products, general merchandise, and miscellaneous unclassified commodities. These seven headings include between 9,000 and 10,000 kinds of commodities; and, as it would be utterly confusing to freight agents and shippers for the railways to have a separate charge for carrying each one of this great number of articles between each two termini in our vast country, the goods have been grouped into ten or eleven classes as a basis for fixing rates. The rates in the case of most articles vary according to length of haul, and weight and class of the commodity.

At the present time most freight is handled by one of three classifications: the "official" classification, which prevails east of the Mississippi River and north of the Ohio and Potomac; the "Southern," which is in force south of the Ohio and Potomac and east of the Mississippi, and the "Western," which applies west of the Mississippi. Some of the business between the Atlantic and Pacific sections of the United States is handled by the "Trans-continental" classification; and in several States the local, intra-state traffic is required to observe classifications promulgated by the State railway commissions. A single uniform classification for the entire country would be desirable if it were a possibility, because producers, manufacturers, merchants and other shippers could more accurately determine the transportation costs of

RAILWAY TRANSPORTATION

getting commodities to or from the markets. This would facilitate trade, and would, also, enable the shippers and the government to detect discriminations in railway rates more readily. Moreover, this would simplify the problem of state regulation.

The establishment of a uniform classification does not seem practicable at the present time, although the conditions now prevailing are far better than those were which obtained in 1887 when the Interstate Commerce law went into force. Until that time nearly every large railway had its own classification, there being about 40 different classifications in the present "official" territory. In order to observe the provisions of the act of 1887 prohibiting unreasonable personal and place discriminations, a consolidation of freight classifications was necessary, and the result was the working out of the Official, Southern, and Western groupings. This was followed, during the years 1889 to 1892, by an attempt to amalgamate these three main classifications, and the few minor ones still in use, into one uniform classification. This effort was unsuccessful, because the industrial conditions in the Eastern, Southern and Western sections of the country were so divergent as to make the establishment of a single classification of traffic seem impossible, unless a large number of commodities in each section of the country were omitted from the classification. To make a great number of exemptions would largely defeat the object of a uniform system. Indeed, at the present time, with several classifications, an unfortunately long list of commodities is omitted from the classes. Coal, livestock and certain other kinds of traffic are very properly exempt from classification; but the railway companies are constantly being urged by men who are developing new forms of production or are opening up new resources to give them the advantage of special or "commodity" tariffs. The railways do not favor such exemptions unless the new traffic cannot be secured without the assistance of a special commodity tariff; but the fact that some of the large railway systems have over a thousand commodity tariffs in force shows how potent are the shippers' appeals.

Freight is designated "local" or "through." A shipment between two points on the same line of road is local freight; while through freight is that which comes to the railway company from some other railway, or is that which starting at some point on one line is turned over to some connecting carrier. Through business is that which requires the services of two or more railways. In general, local freight is short distance traffic, and through shipments correspond to long hauls; but this is frequently otherwise, especially since our railway systems have come to include lines many hundred miles long.

Through Freight.—In the management of their through or "joint" traffic the railway companies have made great advances. During the first two decades and a half of railway history each company owned a short trackage, and freight sent between distant points usually had to be rehandled at several junction points, because each company preferred to keep its equipment on its own lines. This method of conducting business was expensive and added greatly to the delays and risks of shipment. Some method of making inter-line shipments

without breaking bulk became necessary and the need was largely met by the organization of the "fast freight lines" or freight despatch companies. These organizations date from 1855-6; and, although their original character has changed and several have ceased to exist, they still survive in name. The Union Line, the Empire Line, the Merchants' Despatch, and others of a similar character are organizations with which the public is familiar. At the outset the fast freight lines were managed by corporations distinct from the railway companies. The despatch company solicited freight from shippers, provided its own cars, charged such rates as the conditions of competition permitted, and paid the railway companies for hauling the cars. The nature of the services performed by the fast freight lines may be illustrated by referring to the history of the Empire Transportation Company chartered by the State of Pennsylvania in 1865. This company was organized to increase the business done over the Philadelphia and Erie Railway, which connected Sunbury and Erie, Pa. This road was only a part of one of the through routes between the Atlantic seaboard and the Great Lakes and the oil fields of western Pennsylvania. The Empire Transportation Company, in order "to increase convenience, promptness, and safety, in the transfer of property between inland points . . . and points on the Atlantic slope and seaboard and in foreign countries east thereof," built pipe-lines within the oil regions, constructed terminals at the seaboard and the Great Lakes, and organized transportation companies to operate on the Lakes and over the railway lines west of Pittsburgh and Erie. Such an organization as this could perform a useful service. It developed new traffic, it solicited business, it provided itself with rolling stock and thus relieved the railways of supplying specialized equipment at a time when capital was not abundant. The conditions have now changed, however. The railway systems have become so extensive, and their interline relations have been so developed, that the railways are able to perform practically every service which the shipper may require. Every railway will take freight and issue bills of lading for any point in the United States, and, indeed, for many places outside of our country. Most of the despatch companies were brought out by the railways between 1870 and 1880 and converted into "co-operative fast freight lines," which were in reality only joint arrangements among connecting roads to facilitate their through business. Each co-operating road assigned to the joint line a number of cars proportioned to the mileage of its system, and the earnings and expenses of the joint lines were divided proportionately among the constituent companies. These co-operative freight lines thus became essentially an arrangement among certain railways for securing an inexpensive and honest administration of their interline business. This co-operative form of organization put an end to an abuse that was connected with the former independent fast freight line or despatch companies which were frequently owned by the officers and directors of the railways for whom it was profitable to favor the freight line at the expense of the railway corporation.

The consolidation and growth of railway cor-

RAILWAY TRANSPORTATION

porations and the development of vast systems are rendering even the co-operative fast freight lines unnecessary. In many cases they continue to exist, but are regarded rather as trademarks of which continued use is made because shippers have become accustomed to sending their freight by certain routes and by particular bills of lading. In keeping the record of the cars, and in settling interline accounts the freight lines are of service to some companies; but the time is probably not far distant when each company will manage all its freight business directly through its own freight department.

A prominent characteristic of the American railway service is the specialization in the freight equipment. For each commodity (like coal, iron ore, petroleum oil, livestock, dressed meats, fresh fruits, etc.) that is shipped regularly and in large quantities there is provided a type of car constructed with reference to the most economical carriage of the traffic. Most of the special-service cars are provided by the railway companies; but a large part of them is owned by the shippers. In times past even greater use was made of private cars than is customary at present; and even now there are probably 125,000 of the shippers' cars, or one seventh of all the freight cars in the United States. The use of private cars will probably decrease in the future, because a large railway corporation doing business in several States can derive more profit from providing all the equipment required for its traffic than from renting private cars for any considerable portion of its business.

When personal discriminations were generally practised the owners of private cars had a great advantage over other shippers, not only because they offered the railways a large tonnage, and could thereby secure a low rate; but also because the car-mileage exacted of the railways by the owners of the private cars was the source of large gains. The private cars usually are devoted to long-distance one-way traffic, which means a disproportionately large mileage for such cars as compared with the others, and that the private cars must be hauled without a paying load half the distance they are moved. Although the customary car-mileage charge has been reduced nearly one half during the past decade the railways continue to prefer shippers to use the railway company's equipment. From the standpoint of government regulation and the prevention of discriminations, the substitution of the carrier's equipment for that owned by the shippers is desirable.

The volume of long-distance traffic and travel in the United States is so great that each railway company is practically obliged to bill freight and to ticket passengers to points on the lines of many other companies. The freight and passenger cars used in handling this joint and through business move freely over the tracks of numerous companies, and an elaborate system of car-records and interline accounts becomes necessary. In Great Britain, ever since 1850, all joint traffic has been handled on way-bills and tickets of a "clearing house," through which the railway companies settle their interline accounts. This method of doing business and settling joint accounts is economical, and makes secret rate cutting on through business practically impossible. There has been much discussion regarding the adoption of the clearing-house method of

handling through rail traffic in the United States, but the size of the country is so vast and the number of the companies is so great that a single clearing-house for the entire country seems hardly possible. It might be feasible to operate a clearing-house within each of the half dozen leading territorial groups of American railways; and the progressive consolidation of our railways under a decreasing number of managements will simplify the problem of inaugurating the clearing-house method of managing inter-railway traffic.

The Passenger Service.—In many ways the passenger service differs from that of carrying freight. Freight is handled mainly in car loads or train loads and the car or train is started whenever the cargo is completed. The passenger service, however, is performed by trains that run on fixed schedules quite regardless of the number of passengers that may desire to travel at the time fixed for the train to start. This distinction does not apply in all cases because some kinds of perishable commodities are moved by freight trains that are run in accordance with fixed schedules, but in most instances the distinction holds good. In the passenger service more than in the freight business attention must be paid to speed, safety, comfort and convenience. Although quickness and regularity of service is required of the railways by some shippers the chief demand is for cheap transportation and low rates. Consequently, railway companies are under constant pressure to reduce the cost of handling and hauling commodities. In the development of their passenger service, however, the railways are seeking to increase the speed and safety, and to lessen the discomforts of traveling. Probably, American railway companies have underestimated the demand for cheap passenger fares, but they have unquestionably acted upon the theory that excellence rather than economy has been the demand of the traveling public. The result of following these different aims in the development of the freight and passenger service has been that the average freight train load has nearly doubled since 1890, that the average freight train mile revenue has risen nearly 50 per cent, and that there has been a large decline in freight rates—23 per cent during the decade 1890-1900; whereas the number of passengers per train is no greater to-day than it was in 1890, and there has been an actual decrease in the revenue per passenger train mile, and there has been only a relatively slight reduction—7 per cent—in passenger fares since 1890.

Contrary to ordinary belief the American people make comparatively small use of the passenger service offered by the railways. The people of the United Kingdom take nearly twice as many trips each year as the people of the United States do, although there are about twice as many persons in our country as there are in the United Kingdom. The Briton takes 27 rides each year, while the American averages about 7½. As regards the number of trips per year the average per person in the United Kingdom is 27, Belgium 17, Switzerland 15, Germany 12 and the United States 7½. The American travels a few miles more each year than does the inhabitant of any other country except the United Kingdom, but even the people living in such small countries as Germany and France travel almost as

RAILWAY TRANSPORTATION

many miles annually as does the average person of the United States. One way to show the use made by the people of different countries of the railways for travel is to compare the number of miles traveled per mile of the railways. In Great Britain the number of "passenger miles" per mile of road is about 400,000; in Germany, 343,000; in France, 283,000; and in the United States, 72,000. While it is to be expected that the railways serving such densely populated countries as the United Kingdom, Germany and France will have a greater passenger traffic per mile of line than will the railways in a relatively sparsely settled country such as the United States, the foregoing figures nevertheless indicate that the American railways can do much to increase travel in the United States.

One method of accomplishing this would be for the American railways to follow the example set by the roads of Europe and to divide passengers into classes. As a matter of fact, there is some classification in the American passenger service, there being the Pullman service above the so-called first class, and a second class; but Pullman cars are run on relatively few trains, and many roads sell no second class tickets. In all European countries there are at least three classes, and in Prussia there are four, besides a separate class for the military. The trend of traffic has been from the upper to the lower grades as the result of increasing travel by the poorer people and the improvements in the comforts to be secured. In the cheaper grades of service the average passenger fares in the Continental countries of Europe are much lower than in the United States. The average receipts per passenger per mile in Prussia are 1.05 cent, in France 1.02, in Hungary about 1.01 cent, and in Austria, about 1 cent. In the United States the average earnings per passenger mile are about 2 cents.

The success which has resulted from the improvement and development of the lower and cheaper grades of service of the European railways suggests that it might be advisable for the railways in the United States to develop a service below that of the ordinary first class day coach, and to make the fares for this inferior service considerably cheaper than those now prevailing. In order to increase their passenger business in a large way it would be necessary for the railways of our country to make its possible for the masses of the people to travel economically. The demand of those who work for small wages is for a cheap service and not for luxury.

To some extent the demand for a cheaper passenger service is being met by the extension of inter-urban electric trolley lines. In many places electric lines have introduced a service cheaper, slower and less comfortable than that offered by the steam lines, and the result has been the development of an enormous volume of local traffic. There are instances of the construction of trolley lines parallel with trunk line railroads and the development of a local traffic 20 times that previously handled by the steam lines. This enormous traffic by trolley has, however, not lessened the travel by steam roads, but has developed a traffic that previously did not exist.

The Express Service.—In the United States a rather sharp distinction is made between ex-

press and freight traffic although in each case commodities are transported. Express traffic consists of the articles other than mail matter and personal baggage that are carried on passenger trains. Some express goods are carried in train loads but this is exceptional even at the present time; and occasionally ordinary freight is sent as express in order to secure especially prompt delivery. Express companies also sell money-orders payable at any of their offices and they sometimes collect accounts and execute papers. In foreign countries the express business is conducted either as a part of the freight service of the railways or as a part of the postal service. The United States receives no package for the mails weighing more than four pounds except in the case of a single book, whereas many foreign countries accept packages weighing 11 pounds for carriage by mail. The reason why the American railways do not handle the express business is a historical one. During the first decade of the development of the railways in the United States there was no special organization for handling express business. The patrons of the roads, however, began to send packages from one station to another by entrusting them to the conductors or baggage agents. In 1839 William Harnden began receiving parcels for transmission between New York and Boston. The following year Alvin Adams began to compete with him in the New York and New England business. Harnden then began the express service between the United States and Europe, and 14 years later Harnden, Adams, Thompson and Kinsley consolidated and became the Adams Express Company. The American Express Company grew out of a consolidation which took place in 1850. Wells, Fargo and Company started in 1852, the United States Express Company in 1854, and the other important companies organized soon after that date.

The railway companies of the United States found it convenient and profitable to permit the express companies to organize and develop the parcels service. Each railway corporation makes a contract with an express company giving it a monopoly of the express business over the lines included in the agreement. The railway company furnishes the cars and hauls them for the express company and obtains therefor from 40 to 60 per cent of the total receipts of the express company, the percentage of the total receipts paid to the railway being dependent upon the volume of the express business. In the Eastern States where the traffic is heavy the railways receive 40 per cent. In the contract between the express and railway companies it is usually stipulated that the minimum express charge shall be from 50 to 150 per cent above the rates which would be charged for carrying the articles as ordinary freight. In actual practice the express charges average from 3 to 4 times what the freight rates would be.

The necessity for separate companies to perform the express business is no longer urgent. Indeed it is probable that it would be more profitable for American railway companies to develop their freight service so as to include the collection, carriage and delivery of most of the parcels now handled by the express companies. It is also the opinion of many experts that the time has come for the United States

RAILWAY TRANSPORTATION

government to include in its mail service the carriage of parcels up to the weight of 10 pounds. By doing this and by perfecting its money-order service the United States government would with profit to itself and convenience to the public perform a large part of the business now done by the express companies.

The Mail Service.—The transportation of the government mails is an important branch of the railway service. Over 8,000,000,000 pieces of mail matter are now handled annually in the United States mails, and the weight of this mail exclusive of the sacks and equipment used in handling it probably exceeds 350,000 tons annually. Although the United States employs steamships, stage coaches and messengers as well as railways to handle its mails, over 86 per cent of the total weight of the mails and equipment is carried by the railways. On 50,000 miles of railways "railway post-offices" or cars equipped as post-offices are run. These cars are in charge of messengers who sort the mail as it is received and place it in special pouches, there being pouches for each city, and usually pouches for each of many sections of the city. On nearly 120,000 miles of railways department mail cars are operated, and on about 20,000 miles of railways the mails are carried in closed pouches usually in the baggage cars. From these figures it would seem that our mail service makes use of nearly 190,000 miles of steam railways. The messengers and crews in charge of the mails travel nearly 250,000,000 miles annually. The railway post-offices have come to be an indispensable feature of the service. The plan of sorting mail while in transit originated in 1862 with William A. Davis, who then fitted up the first railway postal cars. The advantage of using such cars was quickly recognized and they were soon in operation on the principal mail routes. The postal cars now built are from 40 to 60 feet in length, and the government is constantly increasing the number used. To the extent that the distribution of the city mail can be transferred from the post-offices to the postal cars to that extent the delivery of the mails will be expedited. The payments received by the railways for carrying the mails are determined in accordance with Acts of Congress passed in 1873, 1876 and 1878. The basis of payment is the weight of the mails and the distances carried, and, if handled in full-size postal cars, the number of miles such cars are operated. The following table states the amount of payment received by the railways for different weights of the mails and also indicates the equivalent rate per ton per mile for handling this traffic.

RATES BASED ON THE WEIGHT OF THE MAILS.

| Average daily weight of mails over whole route | Pay per mile per annum | Rate per ton per mile |
|--|------------------------|-----------------------|
| 200 pounds..... | \$42.75 | \$1.171 |
| 500 pounds..... | 64.12 | .702 |

The rate per ton mile received by the railways for carrying the mails declines rapidly with

the increase of the average daily weight of the mails handled. It is because of this that the railway companies to-day are receiving a lower rate for carrying the mails than they formerly obtained although there has been no change in the provisions of the law for 25 years. The average daily weight of the mails is ascertained by weighing the mails for 30 successive days once in four years. The average of those 30 days is assumed to be the average for each day of the year and the payments for the succeeding four years are based upon those figures. As the amount of mail business increases yearly the railway companies during the latter part of the four year period are not paid for as great a weight as they actually transport. It is estimated that they are paid for 91 or 92 per cent of the weight of the mails carried.

The rates allowed for hauling full-size post-office cars and the equivalent rates per mile run by the cars are shown by the following table:

RATES ALLOWED FOR FULL-SIZE POST-OFFICE CARS.

| Length of car | Rate per annum per mile of track | Rate per mile run by cars |
|--------------------|----------------------------------|---------------------------|
| 40 feet..... | \$25.00 | 3.424 cents |
| 45 feet..... | 30.00 | 4.109 cents |
| 50 feet..... | 40.00 | 5.479 cents |
| 55 to 60 feet..... | 50.00 | 6.849 cents |

It has frequently been charged that the government is unduly liberal in its payments to the railways for carrying the mails. For 20 years the United States has annually paid the railways about one third of the total amount of the postal receipts. When compared with the payments made by other countries this rate is not found to be exceptionally large, and while the remuneration made by the government to the railway companies is ample it can hardly be said to be excessive. See POST AND POSTAGE.

The Organization of the Railway Service.—The agency by which the railway service is performed is a corporation, and on account of the complexity and multiplicity of its duties it is necessarily a highly specialized organization. Like other corporations it has departments and officials for the management of its financial and legal affairs, but in addition to this, it includes a special transportation organization to which four duties are entrusted. One duty is the construction and maintenance in proper condition of the roadway and all necessary structures. The second is to provide and keep in proper repair and to operate the equipment which the traffic may require. The third is to furnish the facilities that will enable passengers and shippers to make use of the transportation service, and the fourth duty is to arrange and adjust the relation of the carrier with its patrons in such a way as to further the interests of both parties. Corresponding with each of these four duties there are separate departments of the service within each of which there is a minute subdivision of duties and responsibilities. From the bottom to the top of the service there runs an unbroken line of responsibility, each employee being responsible to his superior, while the president of the company is under the control of the Board of Directors who must give an account of their management to the stockholders. Corporate organ-

RAILWAY YARD SWITCHING

ization has reached its highest stage of development in some of the larger railway systems of the United States. The railways in the United States now employ about 1,100,000 men. Unless agriculture be considered as a single industry it is proper to speak of the railway business as the greatest of all the industries. This vast army of railway employees consists to a large extent of skilled laborers who are well paid, are well organized and are steadily adopting higher standards of living. Their influence upon the progress of American labor is far-reaching and altogether beneficial.

Co-operation in the Railway Service.—The railway service is of such a nature that it must be performed by large corporations. Moreover, it is absolutely essential that these corporations should co-operate with each other; not only must they work together in the management of their joint business, but they must also co-operate in the regulation of their competitive traffic. The history of American railway transportation shows conclusively that there must be co-operation among railways if the public is to receive an adequate service at rates that do not unjustly discriminate between persons, places or classes of traffic. The United States and the several State governments have passed many laws prohibiting the co-operation of competitive railways, but such laws have always been inefficient. The necessity for co-operation among railways grows out of the public nature of the service they perform. Railway transportation being a service of a public nature which may be performed directly by the government or by agents authorized by the State, it must be conducted in such a way as to minimize discriminations between persons and localities. For each railway, to compete independently of other roads, by bidding for traffic is to introduce intolerable discriminations. The United States very properly prohibits railways from making unreasonable discriminations, but it makes the mistake of prohibiting that degree of inter-railway co-operation that is necessary for the establishment and maintenance of equitable charges. While the best performance of the railway transportation service and the prevention of discriminations requires that the railways shall be permitted to co-operate, the conclusion is not to be drawn that the railway corporations should be permitted by the government to perform their service and to make their charges without governmental regulation. The proper adjustment of the relation of the carrier and the public requires the supervision of the service by the government, and the correction from time to time of unreasonable discriminations. This is not merely a theoretical statement, but is a deduction fully warranted by the history of railway transportation.

formation); Stimson, 'History of the Express Companies, and the Origin of American Railroads' (1858); Dabney, 'The Public Regulation of Railways' (1889); Tunell, 'Railway Mail Service' (1901); Haines, 'American Railway Management' (1897); Woodlock, 'The Anatomy of a Railroad Report and Ton-Mile Cost'; Greene, 'Corporation Finance' (1897); Eaton, 'Railroad Operations and How to Know Them' (1900); Keister, 'Corporation Accounting and Auditing' (1897); Whitehead, 'The Railway Auditor: An Outline of the System of Railway Accounting' (1902); Johnson, 'American Railway Transportation' (a volume describing the American railway system, the railway service, the railways and the public, the railways and the State, and including numerous bibliographical references at the close of each chapter).

EMORY R. JOHNSON,

Author of 'American Railway Transportation.'

Railway Yard Switching.—Switching or shunting cars is a term commonly applied in steam railroad yards where freight and passenger trains are prepared for road service and for further distribution of cars at terminal points, the preparation of a train at a terminal point for dispatching to another terminal point and so prepared as to reduce to a minimum extra handling of a train while enroute.

The construction of railroad yards in reference to track arrangements for switching purposes, the equipment of cars and engines, fixed signals, and other facilities requisite to yard operation, have been given much attention by prominent railroad men, and through the periodicals given much publicity, which has done much good in bringing about a higher state of efficiency, but little has been written relative to switching, which, in a general way, means interior operation.

The character of business to be handled regulates the manner in which the switching is performed, therefore, there can be no established rule to govern all yards where switching is done, but taken as a whole, a large per cent. of the rules will apply to all yards and are in effect.

At terminal stations, where trains are received and despatched from the same yard or intermediate yard, the switching is separate and distinct and must, therefore, be divided into two classes as follows:

- | | |
|--|---|
| Make up yard, Trains prepared for road service. | <div style="display: inline-block; vertical-align: middle;"> <ul style="list-style-type: none"> a. Accumulation of loaded and empty cars. b. Inspection and weighing cars. c. Separation of cars into classes. d. Despatch of trains. </div> |
| Break up yard, cars separated for final delivery. | <div style="display: inline-block; vertical-align: middle;"> <ul style="list-style-type: none"> a. Trains from the road to be switched. b. Inspection and seal record of cars. c. Classification by switching. d. Movement to final destination. </div> |

In the make up yard, where trains are prepared for road service and in break up yards, where trains are received from the road, the switching is performed by engines of a type especially adapted to yard service. They are constructed with a short wheel base, which is very essential to the work, as many yard and industry tracks are of very sharp curvature and on which engines of longer wheel base, such as those used on road service, could not move without danger of derailment. They are also of sufficient weight and steam pressure to handle the maximum number of cars received or despatched on one road train.

RAILWAY YARD SWITCHING

In the preparation of a road train, cars are assembled into a receiving yard from various places. Cars are loaded at industries, public team tracks, freight houses, and, after the billing for each loaded car has been prepared, showing the weight, contents, and destination, the cars are collected together by the yard engines, which are assigned to industry and freight house work, and are taken to the receiving yard, where all freight is collected for an outbound movement. The yard, or shifting engines, which perform this and similar work, is all the while under the supervision of the yard master. The crews are composed of the following: one engineman, one stoker, one engine foreman, two helpers. The engine foreman is known as the conductor and the two helpers are known as yard brakemen or yard switchmen. The entire crew is subject to the orders of the engine foreman.

The freight in cars ready for transit, taken from local team tracks, industries, etc., on the road where the switching is done, does not comprise all of the channels from which freight is received, but to the contrary forms only a meagre part of the freight received for shipment. By means of a common interchange or reciprocal arrangement between connecting line roads, which have business relations and are amicable according to a mutual understanding, loaded and empty cars are continually received from connecting roads, which must undergo the same inspection before being switched into road trains as the cars received from other sources.

This freight, being composed of various commodities, live stock, perishable, and dead freight, is then switched into road trains for despatching. It is classified by the switching crews in division or station order, the live stock and perishable freight being given preference and where solid trains of high class freight cannot be run, the train is then filled out by adding additional cars of less important freight, which in railroad circle is termed, "dead freight." This dead freight is added to a train of high class freight until the proper tonnage is acquired to complete a train.

The shifting crews assigned to the make up yards must be men of experience, as a general knowledge of the routing of cars is necessary and can be only acquired by long service and close application to the work, to prevent errors in wrong routing to cars. Cars for the various divisions of a road are switched to tracks which are assigned to a division of a road, the live stock and perishable is switched to tracks assigned for preference trains, dead freight, empty cars, etc., are assigned to other tracks, etc., until there is a complete separation of the freight in building up the road train.

On some terminals, this switching is performed by gravity or hump method, the yard tracks being so constructed as to have an elevation or hump at the head of the make up yard. The cars are detached by the engine foreman singly or in groups, as the classification may require, after which they attain sufficient momentum to gravitate into the yard track to which assigned. Where this method of yard operation is in force, the number of men assigned to an engine is very greatly increased. In yards where heavy business is handled, twenty or more men work with one engine, who bear the title, "Car

riders," their duty being to ride the cars into the track to which it is assigned and reduce the momentum of the cars by applying the hand brake to prevent them striking cars already on the tracks with more force than is necessary to have them couple together automatically.

The switch tracks used in the operation of a gravity yard are usually operated by an interlocking plant, the same being located at the summit of the elevation which affords a clear range of vision for the interlocking operators to all of the tracks in use. The duty of the interlocking operator being such as to require him to work in conjunction with the engine crews in disposing of cars to the various tracks assigned. A switching list is first prepared in duplicate and a copy furnished to the interlocking operator and the engine foreman, which indicates cuts or separations to be made in the train. By this method the engine foreman and crew and the interlocking operator work in unison which is necessary to prevent cars from entering tracks which they do not belong. After each cut of cars or yard train has been switched and the cars travel into the tracks to which they are assigned, the car riders, who protect the cars down into the yard, are collected up by the engine which was used to shove the train over the hump. In some yards a special engine is used for this purpose and the men are collected and brought to the summit of the hump to be ready to protect another run of cars. Frequently two yard engines are used in the operation of gravity method of switching, which reduces the amount of delay in the work and increases the number of cars handled without increasing the number of car riders.

The gravity tracks are constructed on a three per cent. grade for a given distance and then are reduced to a two per cent. grade and the yard tracks to one-half of one per cent. grade or just sufficient grade to carry the cars to the desired stopping point.

When a sufficient number of cars shall have been accumulated to make a train of the required tonnage, a road train crew is then called to move the train, consisting of an engineer, fireman, conductor, and two brakemen.

With the growth of the business and the large increase in the number of cars handled at terminal points, it was evident that something better than the switching list for the guidance of the yard crews was necessary and the side carding of cars was inaugurated to designate the routing and the destination of cars, which was found to be practical and is used to quite an extent. Cards of various shapes and colors are used, each color and shape having its meaning, and it is found to be a large factor in facilitating the work, as the yard men soon become accustomed to the cards, which are securely tacked on to the side of the car, and without having to consult the card way bill or the switch list, which accompanies each loaded car, they are able to direct the car to the track to which it belongs, being guided by the color, design, or number of the side card. These side cards, which are put on by the yard clerks, show the contents and destination of the cars and have no value or particular use after the road train is ready to depart, as it is merely a symbol for the guidance of the men when building up a

RAILWAY YARDS

train, thus expediting the work. This system is called "side carding."

In receiving yards where road trains are disposed of, the character of the business, in a measure, is similar in most respects, as far as yard operations is concerned, to yards where trains are made up for road service. A train for the road, arriving from a terminal point, is switched according to its classification and the class of freight included in the train, its destination, etc., regulates, in a measure, the amount of switching to be performed to break up and dispose of the train. If the train consists of loaded cars for freight houses and team track delivery, very little switching is necessary, for the reason that the cars are immediately placed at the freight houses and team tracks for unloading. Carloads of freight for freight houses are unloaded by freight handlers and is stored in the freight house, the consignees, or owners of the goods, being advised of the arrival of such freight, by the freight agent. Cars loaded with commodities other than merchandise, which are unloaded on the team tracks, are handled by the agent and the owners notified in a similar manner, to release the cars.

Trains bearing cars which are through billed or for local industry switching are more difficult to dispose of and require more switching, as additional classification is required. Therefore, a train consisting of the maximum number of cars to complete the tonnage may have twenty or more classifications in order to properly separate the cars and must be separated on to as many tracks as there may be classifications. Yard trains are thus built upon the classification tracks, subsequently delivered by yard engines. The empty equipments, which do not belong to the road performing the switching, are handled the same as loaded cars for connecting line delivery and are disposed of in a like manner.

When a road train arrives at a terminal station, the seals on all loaded cars are carefully inspected by a yard clerk and a record taken to determine if the seals remained intact while the car was in transit and if the contents of the cars remained undisturbed. The train is then inspected by a car repair man for its physical defects, safety appliances, etc., before the train is allowed to be switched. The broken or damaged cars are marked for the repair track and are switched to tracks prepared for that purpose, which is known as the "Rip" or "Shop" tracks. After the repairs have been completed, the cars are again switched into the train for a delivery by a yard engine to the yard or road to which the car may belong. In further preparation of the train, it is sidecarded the same as cars switched into road trains ready for departure. The cards, which are of various color and designs, also bear numbers—the color designates the road or yard to which the car is assigned; the figure designates the number of the freight house or team track to which the car may be assigned; the color of the card designates the connecting line or local district to which the car belongs. All this is of great convenience to the yard employees in switching, as it only becomes necessary for them to observe the color of the card to guide them as to the general direction which the car is to travel. When the cars are moved to auxiliary yards, the cars are placed at the various freight houses

or team tracks by yard engines, the yard crews being governed by the figures or notations which may be on the side cards.

In drilling cars from road trains in a break up yard and separating them into classes, they are assigned to tracks in the classification yard, subject to transmission to destination as fast as a yard train has accumulated. When yard trains are delivered to connecting line roads with whom the reciprocal arrangements are in effect, the same engine and crew move a train to the home road on their return, eliminating a light engine movement, which otherwise would be necessary.

Thus the yard power and forces are kept continuously in action day and night, as a mere closing down for a short period would result in yard congestion and delay to freight.

W. J. PRINDLE,

General Yard Master, Pennsylvania Lines, West.

Railway Yards. A railway yard is a series of tracks and groups of tracks provided at intervals along a line of railway and at its terminal points for the purpose of switching and storing cars, and the distribution of cars and freight. The intervals between the yards are usually from 100 to 200 miles. The yard includes facilities for changing and taking care of locomotives, and at important points there are also facilities for handling passenger cars and trains, but the principal feature is the freight service. The main features of a railway freight yard are to receive trains passing over the road, to separate and classify the cars for their proper destinations, and to put the cars together into trains for forwarding. The quicker these operations are performed and the less time the cars are detained by them, the higher will be the efficiency of operation of the yard.

Passenger trains and through freight trains require little attention beyond the changing of engines at division points and the inspection of brakes, wheels, etc., to see that the trains are in safe and proper condition. But general freight trains are composed of cars of various commodities and for various destinations; they have therefore to undergo a series of switching movements at intervals to separate and classify the cars. Cars brought in by local trains from stations along the division tributary to the yard must be classified and distributed for outgoing through and local trains over the next division. At junctions with branches or with other lines of railway the incoming cars must be classified and distributed into similar trains for the different routes. At certain yards, also, it may be necessary to break up the incoming trains and rearrange the cars in lighter trains to be taken over the heavy grades of a mountain division. Some yards provide simply for the redistribution of cars in trains, for forwarding over the next division, or for interchange with connecting railways. Others, as at large terminals and cities, may include the distribution of cars to (and their collection from) freight houses, warehouses, team tracks, factories and industrial establishments, coal and stock yards, coal and ore docks or piers, grain elevators, steamship piers, local or district yards, etc. In addition to handling the loaded cars, it is necessary to collect cars which have been unloaded and to distribute empty cars to points where loads await them.

RAILWAY YARDS

Design of Yards.—The design of railway yards is a difficult problem, and especially so in the case of the redesign or enlargement of an existing yard. Many large yards have simply grown by gradual and piecemeal enlargements made without regard to the design of the yard as a whole, and are consequently not adapted for systematic and efficient or economical operation. Within the past few years, however, much attention has been paid to this matter, in connection with the general tendency to increase the efficiency and economy of railway operation. A new yard should be designed with regard to the probable growth of traffic, but also with regard to compactness. If a yard is too large, with tracks of unnecessary length, there will be de-

"body tracks" opening from a diagonal track or "ladder track." The number and length of body tracks will depend upon the character and amount of traffic. Besides these, there will be special tracks and facilities for such work as supplying ice to refrigerator cars, watering and cleaning stock cars, unloading cars, etc. The separate groups must be so arranged in series that the cars will move continually forward in their several switching movements, all reverse movements being detrimental to the highest efficiency and economy of operation. There will be two separate general yards, for traffic in opposite directions, and special provision must be made for special classes of traffic (coal, cattle, perishable freight, etc.) so that fast-freight

Elkhart Yard, Lake Shore & Michigan Southern Railway.

Connellsville Yard, Baltimore & Ohio Railroad.

lay and complication in working the cars through the successive groups of tracks, while the aggregate length of the yard will be excessive, causing considerable trouble and delay in the work. If the yard is too small, however, the tracks will be too crowded for rapid and efficient work, involving frequent rehandling of the cars, while incoming trains may interfere with the regular traffic by being held on the main tracks or station tracks until there is accommodation for them in the yard. In very many cases the design of a yard may be limited by the extent in shape of the land available, and one feature of the problem is to obtain a maximum efficiency on a minimum area. This is of increasing importance in and near large cities, and in some cases it may be found advisable to abandon large city yards (occupying land of high value) and to build new outlying yards with connecting lines to city freight stations or small local yards. The capacity of these city stations and yards may be increased by using freight-houses of three or four stories, the cars being handled by elevators. This has been done in a number of cases in Europe.

The various tracks and groups of tracks form together the yard or "general yard," but each group of tracks for a specific purpose is also called a "yard." Thus a general yard may comprise receiving, separating, classification, storage, repair, advance, and departure yards. Each of these consists of a series of parallel

trains can be made up rapidly and both these and through trains attended to without interference with the work of switching or moving the ordinary cars. The illustrations show examples of railway yards.

Mode of Operation.—When a freight train arrives at a yard, it first enters the receiving yard or track, where the engine and caboose are detached, the work of sorting and distributing the cars being taken in hand by a switching engine and crew. The cars are inspected, and marked as to their disposal, which may include some or all of the following: (1) sent on in through trains over the next division or over some connecting road; (2) distribution to stations along the next division by way or local freight trains; (3) unloaded at the yard; (4) distribution to local freight-houses, grain elevators, factories, coal yards, etc.; (5) held for orders or repairs. The cars are then sent to the separating yard, where those containing the same commodity (grain, lumber, coal, etc.) or those destined for the same point are grouped together on the same tracks. The cars are next passed to the classification yard. If the classification is by commodities, each commodity is sorted into groups; thus a string of grain cars from one track in the separating yard will have the cars of wheat, corn, oats, etc., grouped together on separate tracks in the classification yard. If the classification is by districts, cars for the same district are put together in the

RAILWAY YARDS

order required for delivery at destination. From this yard the strings of cars are drawn to the departure yard to form trains ready to proceed over the road, and the tracks in this yard are frequently provided with air pipes and hose connections for testing the train brakes. An advance yard is sometimes provided to relieve the classification yard when the tracks of the latter become filled. The classification yard is the principal feature, and the separating yard is often omitted. With a large number of tracks in the classification yard, the departure yard is also sometimes dispensed with, except at large yards.

than 15 or 20 cars, for convenience of switching; they are arranged in pairs with paved driveways between the pairs. As a rule the tracks are parallel with the direction of the yard, but in many cases space can be economized by placing them at an angle, the tracks opening from a ladder track. In this way, a number of short-stub tracks may be laid out, facilitating the movement of both cars and teams. This arrangement is also sometimes adopted with freighthouses, the houses taking the place of the driveways. (3) The storage tracks, on which cars are held awaiting orders, should be connected with ladders at each end; otherwise

Enola Yard, Fairview, Pa. — Pennsylvania Railroad.

Length of Tracks.—It is very generally assumed that the length of the receiving tracks should be that of the maximum train hauled over the division served by the yard, but the length varies materially for loaded, partly loaded, and empty trains. If the maximum trains are relatively few, it may be better to make the tracks long enough for the average trains, leaving long trains to be split up on two tracks. The disadvantages of very long tracks have been mentioned, but in the receiving yard these may be reduced by putting crossover connections between the tracks at the middle of this yard.

Yard Arrangements.—(1) The classification yard may have the two ladder tracks parallel, so that all the body tracks between them are of the same length; but there is preference for an arrangement of two ladders at each end, forming a V, and making the middle tracks considerably longer than the others. (2) The team yard, in which are placed the cars to be loaded or unloaded by wagons, is best located convenient to the freighthouses. It should be well paved, to facilitate the movements of wagons, and should be equipped with cranes for handling heavy freight, as well as scales for weighing both wagons and cars. The tracks are generally short, holding not more

there is a tendency to let cars stay neglected at the end of the track, whence it is difficult to remove them, as all the cars on the track must be switched out. (4) The tracks in the repair yard should be short (for convenience of removing cars when ready), holding 12 to 15 cars. They are generally arranged in pairs, spaced about 16 feet and 40 feet alternately, between centres, so as to enable men to work upon the cars. A narrow gauge track for conveying material may be laid in the 40-foot spaces. It is a good plan to provide separate tracks where cars can have slight repairs attended to without the delay of sending them to the repair yard, or can be held until they can be conveniently removed to that yard. Light repairs may be made on the open tracks, but heavy work is usually best done under cover, with facilities provided for heavy lifting.

Track and Equipment.—A railway yard should be well drained and ballasted, laid with heavy rails and kept in good condition, as a good track greatly facilitates the movement of cars. The maintenance of track under such constant traffic is difficult work, and it is good policy to build substantially in the first place. Scales must be provided for weighing cars, which is done while the cars are in motion, and there should be

RAILWAY YARDS

cranes and mechanical appliances for the handling of heavy freight. The efficient lighting of yards is a difficult problem, and as a rule no system of lighting is used. Electricity is the only practical method, but great care must be taken to avoid long shadows, so that tall poles must be used. The alternations of patches of light with dark fixed and moving shadows may be more confusing than a uniform darkness to which the eyes become more or less accustomed. Telegraph and telephone communication between the main yard office, the outlying offices, and the train dispatcher's office greatly facilitate the speed and smoothness of working.

The main tracks may pass through or around the yard (on one or both sides), and should be connected with the yard only at its ends, the connections being fitted with interlocking switch and signal plants. Within the yard the switches are usually operated by hand, but in some cases the switches of a ladder track are operated by levers from a tower. Mechanical operation is not practicable on a large scale, owing to the length and complication of the connections, and the consequent difficulty of working. At large classification yards, however, compressed air and electricity are occasionally used for operating the switches, which are controlled by push buttons or small levers grouped in an elevated tower.

Switching Cars.—The switching or moving of cars from point to point of the yard is effected by locomotives, but in sorting or classifying them three methods may be used: (1) By drilling; the engine being coupled to the rear of the train and running it to and fro on a "drill track" leading to the ladder. Each car, or cut (group) of cars, is uncoupled in turn and runs from the train onto the ladder and into its proper track. (2) By poling; the engine runs on a track parallel with that on which the train of cars stands, and pushes each car (or cut of cars) onto the ladder track by means of a swinging pole attached to the engine or to a poling car coupled to the engine. This avoids moving the entire train for each switching movement, as is done in drilling. (3) By gravity; the cars being allowed to run down an incline or grade. In each case the momentum of the car carries it along the ladder and into the proper classification track, the switches being opened by the switchmen. A slight grade is sometimes used along the ladder to assist the movements of cars. As a rule, a brakeman rides the car to check its speed and stop it at the proper point, preventing damage to cars and contents by running the cars together at high speed. At some large yards, an engine runs to and fro on a special track to bring these men back, thus saving time.

Gravity Switching.—Where the ground at the site of a yard is on a slope, the cars may be started by a locomotive at the upper end and allowed to run by gravity direct to the classification tracks and thence to the departure tracks without further assistance. This plan has been adopted abroad in some notable cases, but there are very few examples in this country. This system of complete classification of cars into both district and station order entirely by gravity movements was first adopted, in 1873,

by Mr. Footner, for the extensive Edge Hill yards of the London & Northwestern Railway, near Liverpool (England). The main part of the yard is on sloping ground, and the cars delivered at the upper end pass through the separating and classification yards (or "gridirons") by gravity, being delivered in proper train order on the departure tracks. From the receiving yard, the cars pass to the separating yards, where each track receives the cars for a particular train. Beyond these are two classification yards through which the cars of each train are passed so as to put them together on the departure track at the foot of the slope in proper order for the train.

Where the natural grades are not suitable for this system, an embankment may be built to form an artificial summit (or "hump" or "camel-back"), having the necessary grades to move the cars by gravity. This is said to have been introduced first in Germany, in 1876, and is now very extensively employed in this country. With proper operation this "hump" system will do the work of handling cars through large yards quicker and at less cost than either drilling or poling, besides resulting in less damage to cars and their contents. The "hump" system is generally employed simply for the classification of cars, the embankment and summit being located on the line of the tracks leading from the receiving yard to the classification yard. There is an easy ascending grade on the side approached from the receiving yard in order to close the cars together and so facilitate uncoupling. Beyond the summit there is a short steep descending grade followed by easier grades continuing along the ladder track to the classification tracks. A train of cars is slowly pushed up to the summit, each car or cut of cars being uncoupled and acquiring an impetus on the short steep down grade which is sufficient to run it into the proper classification track. The grades vary with traffic and climatic conditions, and range from $2\frac{1}{2}$ to 4 per cent. for a distance of about 200 or 300 feet, beyond which a grade of about 1 per cent. extends along the ladder track. Connecting tracks provide for the movement of trains which do not require to be classified. Loaded cars run more easily than empty cars, and all cars run more easily in summer than in winter. Track scales are frequently located on the gravity track, to weigh cars as they pass. The cars on any one track in the classification yard are, as a general thing, not arranged in proper order for handling in trains, so that a considerable amount of shifting approval, but the second gravity movement might be adopted with success for large yards on sloping ground where the cars would move continually by gravity (under control of brakes) instead of having to be pushed up an incline for each summit or gravity track. This would in fact be the continuous gravity system above described.

Buildings.—The buildings required for freight traffic include those for unloading inbound freight from the cars and for loading outbound freight into cars. These are served by driveways for teams. The inbound freight-house must be wide enough to give a proper amount of space for holding freight (50 feet is considered a good width), and usually re-

quires not more than two tracks. The outbound freight-house should be narrower in order to decrease the amount of trucking (25 feet is considered a good width). There is also sometimes a transfer-house for taking small lots of freight shipped in separate cars for the same point, and transferring them to one car, thus getting one full load and releasing the empty cars for service. Where the buildings have doorways at intervals, cars must be "spotted" or carefully set to bring their doors opposite those of the freight-house. This may be avoided by putting a platform outside the house, or by making the track side of the house a series of continuous openings, separated only by piers or columns and fitted with rolling or folding-doors. As many as four rows of cars can be loaded by running trucks through the cars, loose bridges being thrown across between their doors. A very common arrangement is to have the inbound and outbound house parallel, with from three to six tracks between them, and a trucking platform between the tracks. At outbound houses where a great number of cars are required, the trucking of the loads from the freight-house to the cars may be facilitated by arranging a number of stub tracks with the freight-house at their ends; the tracks are in pairs with covered platforms between the pairs of tracks.

Special Facilities.—At large lake or ocean ports, special facilities are required for transferring freight from cars to lighters, barges, and ships. Sometimes, also, there are yards not accessible by tracks, but to and from which cars are carried on large floats. For such work open and covered piers, ferry transfer slips, etc., are required. Coal piers and ore piers may also be required, and these usually have the tracks high above the water, being reached by inclines. The cars deliver the coal, etc., into bins or pockets, from which it is discharged by spouts or chutes as required. In some cases, these piers have machines for unloading coal from cars or ore from vessels into cars. Loaded cars for a coal pier are distributed in a yard with a number of short tracks, so that cars with the same grades of coal may be put together. The empty cars may be placed on a smaller number of long tracks, as no sorting is required. At grain elevators, provision must be made for the steady supply of cars without interfering with yard work. For this purpose a special yard or set of tracks for grain cars to be loaded or emptied is often provided.

Passenger Yards.—Passenger cars and trains must be provided for independently of the freight traffic, but these require little switching except at terminal points where trains are made up or broken up. At these points, the passenger car yard requires tracks for storing and handling the cars, and for cleaning them, as well as for light repairs. The cars may be turned on a turntable (independent of the locomotive turntable) or on a Y-track, the latter being specially convenient where entire trains have to be turned, as it saves a considerable amount of time. The storage tracks should be connected with ladder tracks at each end, but car cleaning tracks are often stub or dead-end tracks, with a supply-house across the end. These tracks should be long enough to take a complete train. Tracks are allotted for or-

dinary cars and for dining, sleeping, parlor, and other special classes of cars. The car-cleaning yard is paved, and is generally supplied with water, steam, gas, and air pipes and electric cables for washing, heating, and lighting, testing the brakes and cleaning the upholstery by the pneumatic process. These pipes are laid between the pairs of tracks.

Locomotive Facilities.—Railways are divided into divisions of 100 to 200 miles in length for operating purposes, and as each division has its own locomotive equipment for both passenger and freight trains it must have facilities for cleaning, storing, and handling the locomotives at the end of their trips. These facilities are usually provided in connection with a freight yard. When an engine has delivered its train into the receiving track of the yard, it is detached and run upon a special track, where it is inspected. It then passes to the ashpit, where the ashpan and grates are cleaned; thence to points where it takes coal, water, and sand. It then usually goes to the engine-house, where it is turned on a turntable before entering the house. Here it is cleaned, has light repairs made, and is held until needed for a return trip. At yards where many engines remain for only a short time before starting on the return trip to their main headquarters, they are sometimes placed on storage tracks in the open air, being sent to the round-house only when repairs are required. These storage tracks may be a series of parallel tracks or radial tracks served by a turntable. As a rule the engine-house is in the middle of the yard, and is of circular or segmental form, with tracks radiating from a turntable. Rectangular houses are, however, employed in a number of cases. The cabooses of a freight train is changed at the same point as the locomotive, and the yard must have a special arrangement of tracks to receive and store the cabooses; a good arrangement is to put these tracks on a slight grade so that the caboose can be run by gravity to the rear of an outgoing return train.

Author of 'Railway Track and Track Work.'

Railways, American. See AMERICAN RAILROADS; RAILWAY SYSTEMS IN THE UNITED STATES.

Railways—Early History. Railroads had their practical origin in England as long ago as A.D. 1600, although at that time they were practically a rebirth of an undeveloped idea advanced by the early Romans. As strange as it may seem, our modern steel-ways and luxurious methods of land traveling had their origin in the industrial railways that were first roughly constructed to simplify the transit of coal from the mines in Durham and Northumberland, England, to shipping points on the Tyne and Wear. At first, owing to the very heavy roads, planks were laid along the bottoms of the ruts in the roads. The rough carts, fitted with clumsy wooden wheels or rollers and laden with coal and ore naturally made far better progress than formerly, and it was but a little while later, in 1676, that the planks were placed on the level of the roads with sleepers and cross ties laid underneath at fairly regular intervals. As an old English writer puts it, planks of timber were laid "from the colliery to the river, exactly straight and parallel, and bulky carts were made

RAILWAYS, ELEVATED

with four rollers fitting the rails, whereby the carriage was so easy that one horse would draw down four or five chaldron of coals." This method of construction was again improved by filling in the spaces between the "ways" and sleepers with dirt so as not to interfere with the progress of the horses and mules. At this stage of the development of transportation the railroad was known as the "wayleave," and it was found that a horse could easily pull a load of 42 cwt., as against 17 cwt. over the old rough roads. These improved thoroughfares were made across fields, the proprietors of which received a certain rent for the right of way. They underwent little or no mechanical improvement until about 1700, when the wooden beams were clothed with long slips of iron to prevent excessive wear. A more complete improvement, about 1740, was the substitution of cast iron rails fixed in parallel lines on cross wooden sleepers. This construction became general in mining districts by 1775; yet railways did not attract attention as being suitable for general traffic, owing principally to the general interest then displayed in canals.

With the use of cast iron rails the method of traction was improved. Instead of a single large wagon, several smaller wagons were linked together (the germ of the modern train) and flanges were put on the wheels instead of the rails, with a marked increase in traction. Until the invention of a self-acting steam carriage by Richard Trevethick in 1802, the draft continued to be by horses. From 1802 to 1811, numerous patents were taken out leading up to a realization of the fact that locomotives running with smooth wheels on smooth rails could, by friction, draw heavy loads up moderate inclines. In 1814, locomotive power was employed by George Stephenson on the Killingworth Railway with success and was soon afterward applied on the Stockton and Darlington Railway, for which the first Act of Parliament was passed in 1821. This was the first railway to transport passengers, and even with its large measure of success, the locomotive was still a very imperfect machine, with a rate of progress but little faster than the walk of a horse. Acceleration, the main desideratum, was attained by a very simple contrivance, sending the waste steam up the chimney so as to cause a draft in the fire and a resultant rapid generation of steam. By this appliance, with the multi-tubular boiler, the locomotive entered on a new epoch. Notwithstanding the proved feasibility of railroads the public at large were slow to give heed, and in a large measure remained skeptical. The idea of extending railroads for general traffic was perhaps first conceived and urged on the public by Thomas Gray of Nottingham, in 1823 and 1824. In the latter year, Joseph Sanders of Liverpool issued the prospectus of a railway from Liverpool to Manchester, which line, after much opposition, was sanctioned by legislature and opened for traffic in 1830. The success of this line, provided with some of Stephenson's improved locomotives, was immediate and complete and was the beginning of the great commercial enterprise which has since assumed such great importance.

The pioneer American railroad constructed for public use was the Baltimore and Ohio,

chartered in 1827, with 13 miles open for traffic in 1830. Five years later, the length of this road was 135 miles. The Charleston and Hamburg railroad in South Carolina was chartered in 1829 with a completion of 137 miles in 1834. The line from Albany to Schenectady, 17 miles in length, was opened in 1831 and five years later Albany and Utica were connected by rail. In 1842 Buffalo was reached. The Columbia Railroad, the first division of the present Pennsylvania Railroad System, connected Philadelphia and Columbia in 1834. This road was built by the State and was a link in the through route, consisting of canals and railroads, connecting Philadelphia with the Ohio River at Pittsburg. The Camden and Amboy, connecting Philadelphia with New York, was chartered in 1830 and completed in 1837. The road from Philadelphia to Baltimore was chartered in 1831 and completed in 1837. The Reading Railroad, built mainly for coal transportation, was chartered in 1833 and opened for traffic in 1838. American locomotives were first built in 1830 and were adapted to the light rails, steep grades, and sharp curves of the American tracks. As traffic conditions changed, the engines, cars, and equipments were made to conform to constantly changing designs. American railway mileage presents an interesting aspect. In 1830 there were 23 miles in use; in 1840 there were 2818 miles; in 1850 there were 9021 miles; in 1860 there were 30,635 miles; in 1870 there were 52,914 miles; in 1880 there were 93,296 miles; in 1890 there were 163,597 miles; and from that date to the present time there have been added about 60,000 miles. The 70,000 miles of railroad built in the United States in a single decade (1880 to 1890) was a marvelous achievement unparalleled in the economic history of any other country in the world.

The railway systems of the United States now comprise about 225,000 miles of line, being about two-fifths of the railway mileage of the world. Estimating the cost of railroad property the world over at \$35,000,000,000 it is found that the American Railroads constitute about \$12,000,000,000 of this value. See AMERICAN RAILROADS.

Railways, Elevated. Elevated railways presented one of the first potent factors for the solution of the problem of adequate transportation for passengers between points in great cities. The street railway was an earlier factor, but it met the growing inconvenience of congested streets in only a partial degree, affording but temporary relief. In New York, which city possesses the most extensive system of elevated railways in the world, without taking account of the large system in Brooklyn, now a part of the greater city, two means of relieving the streets of some of the burden of passenger traffic began to be considered as long ago as 1860. Two possible solutions presented themselves, one being to carry it underground through tunnels, and the other to carry it over elevated structures. The former met with more favor at the outset, but the first underground project undertaken was speedily abandoned. Considerable ridicule was expended upon the other idea, but in spite of it an elevated railway, with a single track, was built from Battery

RAILWAYS

place through Greenwich street and Ninth avenue to 30th street in 1866 and 1867, and opened to travel on 2 July 1867. It was operated by means of a cable for a short time, when steam locomotives were substituted as motive power. It did not gain popularity as an aid to local travel, and its lack of success caused it to pass into the hands of the sheriff in foreclosure proceedings, and it was sold for the benefit of creditors in 1871.

The West Side (Patented) Elevated Railroad Company, as the corporation which built and operated this pioneer elevated line was named, was succeeded by the New York Elevated Railroad Company, organized 3 Jan. 1872, under a charter granted by the State legislature the year before. A few months later, on 17 June, the Gilbert Elevated Railroad Company, which obtained a charter earlier in that year, was organized to build a line projected by Dr. Rufus H. Gilbert, and which was planned to be a pneumatic tube railway, suspended from lofty arches. For some reason the pneumatic tube idea was abandoned, sustaining at first a modification which, by cutting off the upper half of the tube, made it a mere trough wherein the cars were to run, and it was decided to build a simple elevated railway. Meanwhile there had been not only lack of encouragement for this sort of enterprise, the West Side experiment not having succeeded yet in overcoming popular prejudice, but there was antagonism on the part of property owners who would be affected by the construction of such railways, and there was friction also between the two existing companies. Litigation assisted to complicate and delay matters.

This was the condition of affairs when, in 1875, the State legislature passed what is known as the Husted Act, which provided for a commission to decide as to the necessity for an elevated railway system in New York city, and to determine proper routes. Under this act a commission was appointed by the mayor of the city on 1 July 1875, and after a number of hearings given to all who favored or opposed such a system the decision arrived at was a favorable one. The commissioners announced on 11 December that their work was ended, the routes which they selected being four in number and including respectively Ninth, Sixth, Third and Second avenues. The work of building the lines was assigned to the two companies then existing, and both companies entered at once upon active construction and into equally active litigation, while each was under the necessity of defending the constitutionality of its charter against the attack of citizens, who were determinedly opposed to both. The New York Elevated had extended its line from the South Ferry to 61st street and Ninth avenue in 1876, and had opened it for travel to 50th street. About this time the enterprise enlisted the interest of Cyrus W. Field, who secured a controlling interest in the company in the spring of 1877. The same vigor and determination that marked his connection with the first Atlantic Telegraph Cable was displayed here, and much of the credit for the eventual success which attended the new departure in urban passenger traffic was accorded to him.

Rivalry between the two existing companies had created much business for the courts in the

meantime; the constitutionality of their charters was questioned; and there were injunctions and counter-injunctions. The Court of Appeals finally was asked to pass upon the constitutionality of the charters, and it sustained them both by a decision which was unanimous. All injunctions were dissolved and work was pushed forward, not only on the pioneer West Side line, but also upon the Sixth avenue line, which had passed from Dr. Gilbert's control and was known now as the Metropolitan Elevated Road. This line, extending from Rector street to 59th street, was opened 5 June 1878. During 1879 the New York Elevated opened its West Side line to 83d street and constructed its Third avenue line which was opened to 129th street the same year. By this time the new means of travel within the city had commended itself to popular favor to such a degree that the permanency of the enterprise was assured. The Manhattan Elevated Railway Company, organized under a Rapid Transit Act, passed in 1875, and chartered on 29 December of that year, took a lease of the roads owned by both the New York Elevated and the Metropolitan, the lease dating from 1 Feb. 1879. From that time the entire elevated system of New York city, of course not including the Brooklyn system, has been known as the Manhattan Elevated Railway. In 1880 the Ninth avenue line was opened to 155th street; a spur from Chatham Square created an additional terminus for the Third avenue line at City Hall; a branch of the same line at 34th street afforded connection with the Second avenue line, which it crosses below grade, and gave access to the Long Island City Ferry from both lines; and a branch from the Third avenue line at 42d street connected with the Grand Central Railway Station.

Financial difficulties, which had repeatedly beset the companies which had undertaken the development of this already gigantic project were of such magnitude in 1881 that the Manhattan went into the hands of receivers on 14 July. After the difficulties had been straightened out and a reorganization of the company had been effected, each year was marked by extension and improvement of the service until the system became what it is in this year, 1904, an elevated railway consisting of four main lines with branches, its total trackage being 117.14 miles, divided as follows: Main lines and branches, two tracks (each 37.68 miles), 75.36 miles; third track, used for express trains, 15.19 miles; sidings, 26.59 miles. The southern terminus of all the lines is at South Ferry. The Sixth and Ninth avenue lines run through Battery Park to Greenwich street, diverging at Morris street, whence the Sixth avenue line extends through Church street to Murray street, through which it reaches West Broadway; it traverses this thoroughfare to 3d street, passes through 3d street to Sixth avenue, which it follows to its terminus at 59th street, the station being at 58th. A branch running westward through 53d street connects it with the Ninth avenue line. From Morris street the Ninth avenue line runs through Greenwich street to Ninth avenue and through that avenue to 110th street, where a double curve on a very high structure carries it into Eighth avenue, which it follows to the terminus at 155th street. The Second and Third avenue lines are one from

RAILWAYS

South Ferry to Chatham square. After leaving the ferry they make a sharp turn into Front street; thence through Coenties slip and Hanover square they enter Pearl street, which they follow to and through the New Bowery to Chatham square. They diverge here, the Third avenue line continuing through the Bowery and Third avenue to the Harlem River. At 34th street passengers desiring to reach the Long Island Ferry transfer to a "shuttle" train; and at 42d street another "shuttle" train conveys transfer passengers to the Grand Central station. Trains from City Hall follow the same line, and passengers are transferred at Chatham square to the Second avenue line if they desire it, as well as at the two other transfer stations mentioned. From 129th street at the Harlem River the Third avenue line continues northward, crossing the river by a fine bridge, open also to foot passengers. North of the river the line runs over a private right of way to Third avenue at East 148th street, whence it follows the avenue to Pelham avenue in Fordham, opposite the entrance to St. John's College. Pelham avenue is practically the end of the line, but from this point there is an extension to the Botanical Gardens in Bronx Park, about a half mile farther north. The Second avenue line, after leaving Chatham square, passes through Division, Allen and East 23d streets to Second avenue, through which it continues to the terminus at 129th street and the Harlem River, where passengers going further north transfer to the Third avenue line. Transfers are made at 34th street to either the Long Island Ferry or the Third avenue line via the branch operated on that street. Down-town passengers on either the East or West Side are transferred at South Ferry to up-town trains on the other side. There is also a system of transfers to the surface lines at various points, the transfer costing the passenger three cents extra.

Until 1901 steam locomotives were relied upon entirely for motive power. The matter of substituting electricity began to be agitated in 1885. The first experiments were made with a motor invented by Leo Daft which was kept in service intermittently on the Ninth avenue line, between 14th and 50th streets, from 27 Aug. 1885, until 19 October, when a series of carefully recorded daily runs was made, continuing, except on Sundays and election day, until December 22. The object of this series of runs was to ascertain measurement of coal consumed, etc. The Daft motor derived its power from an insulated third rail. It did not commend itself to the management of the road, and the inventor was unable to make such improvement in it as to secure its adoption. During the latter part of 1886 F. J. Springer operated an electric car successfully on the 34th street branch; and in 1893 an electric locomotive designed by J. B. Enty which was operated by current derived from storage battery, or from a third rail, as might be found necessary, was tried on the same branch with excellent results, but neither of these inventions was regarded as wholly satisfactory. While New York led in adopting elevated railways, it permitted Liverpool, an English city, to be the first in adopting electricity as motive power, the Liverpool Overhead Rail-

way, completed in 1893, adopting it at the outset. In the same year the Intermural Railway, a feature of the Columbian Exposition at Chicago, made successful use of electricity in the operation of its cars. It was not until the spring of 1899 that the Manhattan Railway decided to use electricity, and the change from steam as motive power was made gradually, the first trains operated by electricity being run over the Third avenue line in 1901. It had already come into use on the elevated railways in Brooklyn. The number of passengers carried over the system at the present time aggregates far in excess of 255,000,000 yearly, and the daily average exceeds 700,000. The system is under lease to a corporation named the Interborough Railway Company, chartered May 6, 1902.

Brooklyn, which is now one of the boroughs of New York city, has an extensive elevated railway system which, like that in Manhattan and the Bronx, as the two boroughs comprised within the former limits of New York are called, has grown out of independent enterprises which finally consolidated. The first company was chartered 26 May 1874, under the somewhat peculiar name of the Brooklyn Elevated Silent-Safety Railway, afterward changed to the Brooklyn Elevated Railway. It encountered vicissitudes, chiefly financial, and was reorganized 29 May 1884. Other companies were chartered prior to the date last mentioned, and several later. The Brooklyn Union Elevated Railroad was chartered 30 Jan. 1899, to take over the properties of the Brooklyn Elevated, the Union Elevated, and the Seaside and Brooklyn Bridge Elevated railroads. On 7 July, in the same year, the Kings County Elevated Railroad was chartered to succeed an earlier company of similar name. This company was reorganized in July 1899, absorbing the Fulton Elevated Railway. Early in May 1900 this company acquired the Sea View Railroad, and subsequently it and its acquisitions were merged in the Brooklyn Union Railroad, which is, at the present time, a part of the entire system of elevated and surface lines operated by the Brooklyn Rapid Transit Corporation. The first elevated line in Brooklyn was opened in May 1885. At the present time the various lines comprised in the system have termini at Fulton Ferry, the New York and Brooklyn Bridge, the Broadway Ferry, the Williamsburgh Bridge, Ridgewood, East New York, Woodhaven (where trains follow the New York and Rockaway Beach Railroad to Rockaway), and at 65th Street, Bay Ridge. All trains to and from the bridge either traverse the full length of the bridge to New York, or transfer there to the bridge trains, which were operated formerly by the bridge authorities. The same conditions exist in regard to trains arriving at or leaving the Williamsburgh bridge, except that the authorities have not undertaken at any time the operation of the railways on that structure. The total length of all the elevated lines in Brooklyn is 28.70 miles, with a total trackage of 67.82 miles. Electricity was introduced as motive power in July 1900.

Chicago opened its first elevated railway in October 1893, the pioneer company being the Lake Street Elevated Railway, chartered 24 Aug. 1892. Other companies were subsequently

RAILWAYS

organized, and there has been here, as in New York and Brooklyn, a series of reorganizations and consolidations which have given to the city a large and convenient system. It is operated by electricity.

Boston also has a fine system, which from its opening has been operated by electricity. The building of an elevated railway system was discussed in Boston as early as 1876, but popular opposition and business interests combined successfully for years to defeat any action by the State legislature, which alone was competent to give the necessary authority. The Boston Elevated Railway Company obtained a charter, finally, in 1894, and the road, which was opened 10 June 1901, was constructed in a little over two years. Its total length is about six and two-thirds miles, and the total trackage, including sidings, is something over 16 miles.

The elevated railway in Liverpool, England, to which reference has been made previously, was completed in 1893, and was the first in the world to use electricity as motive power.

All of the elevated railway systems mentioned thus far are similar to the ordinary railways, the tracks being constructed upon the same principle, but with somewhat lighter rails, and carrying lighter rolling stock. Their distinctive character is derived from the fact that they are carried upon structures of iron or steel, which practically are bridges or viaducts. The proposition to improve them by the introduction of a monorail system has occupied the attention of inventors and railway men for many years. The Meigs single rail system was one of the earliest to attract general attention, and Joe V. Meigs, its inventor, had the backing of such men as the late Gen. Benjamin F. Butler in his efforts to have it approved by the Massachusetts legislature and adopted by the Boston street railway companies. During the winter of 1879-80 a large and successful working model was exhibited to the public in a large loft, with no charge for admission; and in 1886 an experimental railway about one quarter of a mile in length was erected in East Cambridge, with curves, switches, etc., the operation of the system as shown thereby being quite satisfactory to a large proportion of the many people invited to ride upon it. Nevertheless it failed to commend itself fully, and was not considered when Boston finally was ready for elevated railways. The system, as Mr. Meigs once explained it, consists of turning the ordinary double-rail track up on its edge. Horizontally revolving wheels, in contact with the sides of the upper rail, or stringer, furnish the motion, while the car is supported upon rails placed on each side of the lower stringer by wheels having a groove of 45°, giving the wheel contact with both the top and side of the rail as it revolves upon an axle placed at an angle of 45°. The running gear, it is thus shown, bestrides the track, and one of the advantages claimed for the system is that if the supporting wheels should give way in part or altogether the car would remain upright upon the track.

Eugen Langen's monorail system, the main feature of which is the suspension of the cars beneath the running gear, has been in experimental operation since 1900, on a line from Barmen to Elberfeld, Germany. This line is 8.24

miles long, with 18 stations. It is operated electrically, and the consumption of electric power is relatively small, while high speed is quickly attained. On this railroad the cars are so suspended that even in case of a mishap to the carriers they cannot fall.

Howard Tunis is the inventor of a monorail system adopted for a line in course of construction during 1904, the termini of which will be Baltimore and Washington, D. C. It will be operated by electricity, and the current will be derived from an overhead trolley which will assist also in holding the cars upright as they travel over a single rail, laid upon the ground as in ordinary railroad building. The line will be an experimental one to the extent that upon its success will depend the building of similar lines in all directions from Baltimore and Washington.

EDWARD S. FARROW,

Consulting Railroad and Mining Engineer.

Railways, High Speed. By "high speed railways" is meant those on which it is attempted to obtain speeds considerably in excess of those customary with the best equipped express trains. There has been a gradual increase in the speed of all railway trains with the development of the art. The roadbed and the track have been improved and made heavier, cars have been made stronger, the running gear has undergone marked changes, and the locomotive has been made heavier and more powerful, all of which have contributed to the greater speeds now common. But the changes have been gradual. There has been no sudden increase which in the limited meaning of this expression could properly be called high speed operation. Except in a few notable instances, attempts to secure high speeds have been merely isolated experiments in which a train has been run at an exceptionally high velocity, which, however, was maintained for a short time only.

Such tests have not been productive of any change in operative methods, though they have shown that a train would run safely on a good track at speeds considerably above those customary, and they indicated that the power required was less than had been supposed. In such tests the locomotive is limited by the steaming capacity of its boiler, which in our present designs is not great enough to supply the heavy demands made by the engine. This is the difficulty standing in the way of any great decrease in the speed of steam-drawn trains. It is known that the track and the cars will stand the strain and the engine can safely make the necessary number of revolutions per minute, but for this it requires more steam than the boiler can supply and it is difficult, if not impossible, to increase the boiler capacity to any extent.

This limiting factor is not present in an electrically operated train and the possibility of thus obtaining a greatly increased speed was recognized as soon as the success of the electrically operated street car had been demonstrated. In this case the supply of power is limited only by the power of the station, which can be increased indefinitely, and by the current which can be collected from the working conductors. The speed then depends upon the

RAILWAYS

size of the motors and the track construction. A number of attempts have been made to see what could be done in this direction in some peculiar track construction being resorted to. It will, however, be sufficient to take up the first and the last instances.

About 1866, a company known as the Electro-Automatic Railway Company, was organized in Baltimore, Md., to develop a high speed automatic parcel express between large cities. An experimental track, circular in shape and about two miles in circumference, was constructed at Laurel, Md. The gauge was 28 inches, the weight of rails 16 pounds to the yard. Wooden guard rails were laid alongside the running rails and a vertical framework on both sides of the track supported by means of a wooden stringer a light third rail, head down, over the centre of the track. This served as the working conductor and it was thought would hold the car on the track. In this latter duty it failed, and the whole track construction was found to be far too light for the purpose for which it was intended. Current was returned through the track rails.

The car was a steel box, 16 feet long, 24 inches high and 30 inches wide, with pyramidal ends. It was mounted on three axles with 28 inch wheels, and on each axle was placed a 20 horse-power direct current motor. Later the central motor was taken off. The car weighed complete, three tons, and the motors were designed for a speed of 3,000 revolutions per minute, which would give a car speed of 250 miles per hour.

The road was tested in the fall of 1889. Speeds up to 115 miles per hour were obtained, but it was found impossible to keep the car on the track when moving at high velocities. On the last test it left the track when moving with a speed of 115 miles per hour, wrecking the car and 1,000 feet of the track. With a track at all suited to the work, the car could have maintained a speed of 120 miles per hour indefinitely. The engineer in charge of the test advised building a heavier track and car, but as the necessary money was not available the work was stopped.

The tests, while not giving much data, served to show that the train resistance formulae then in use were not applicable to high speeds. For fuller information, consult report of 'High Speed Electric Railway Work,' by O. T. Crosby; Transactions of the American Institute of Electrical Engineers (Vol. VIII., 1890-1).

The latest tests of importance are those begun in 1901 on a 14 mile stretch of track between Marienfeld and Zossen, near Berlin, Germany. The road is nearly straight, with slight grades. The track was first laid with 70 pound rails on iron ties, but this proved unable to stand high speeds and was relaid with 92 pound rails on iron chairs, spiked to wooden ties. The old rails were laid as guard rails on the inside, but from later tests this precaution seems to have been unnecessary. The track is ballasted with broken basalt. Over this track a car mounted on two three-wheel trucks, each truck equipped with two 250 horse-power three-phase motors, was run at various times at increasing speeds until on 6 Oct. 1903, a speed of 126 miles per hour was reached. Later in the month higher speeds, in one case a little over 130

miles per hour, were reached, but unofficially. The car carried a number of observers and ran quite smoothly. The curve was taken at a somewhat reduced speed. During the fastest runs about 1,000 horse-power was developed by the four motors.

The car weighed about 100 tons. The motors are supplied with current at from 1,150 to 1,850 volts from transformers on the car, which reduce the line voltage from 14,000. Current was collected from three line wires by means of two sets of bow contacts. The complete data and computed results of these tests have not yet been made public (March 1904), but the success of the experiments has induced a number of German steam railroads to plan for higher speeds on their existing tracks. In the United States, the New York Central Railway, acting with the General Electric Company, is planning to carry out a similar investigation, and will, if possible, exceed the German speeds. The German tests demonstrated the safety of trains at 125 miles per hour on a straight well-laid track and showed that the requisite power could be collected without difficulty. It is evident that such speeds can be allowed only on a road having no grade crossings, and a change in signaling methods will be necessary to enable the engineer to bring his train under control within the block. The probable financial success of such high speed lines may properly be questioned. No doubt they would carry much, if not all, of the long distance traffic. For short distances they are not feasible. They will be expensive to operate and will probably not greatly increase the present traffic. However, the tendency is toward higher speeds and eventually the public demand will bring it about.

WM. HAND BROWNE, JR.,
'*Electrical Review*,' *New York*.

Railways, Inclined and Mountain. Inclined and mountain railways are similar in their object—the ascension of heights by railway carriages; but the term, "inclined railway," is commonly applied to a line of rails and cars supported on or against the steep side of an elevation, and used to carry passengers and also live stock and vehicles to and from the top of the elevation. Such are the inclined railways on the south side of the Monongahela River at Pittsburg, and on the New Jersey side of the Hudson River, opposite New York. The inclined railway is one of the devices for facilitating travel in and about cities, and bears about the same relation to a mountain railway that a ferry-boat does to a coastwise steamship. It can be propelled by cable, with steam as the motive power, or by electricity. The use of the inclined railway is not as general as might be expected, considering the extensive tracts of land in the vicinity of New York and other cities which the inclined railway would make readily accessible.

The mountain railway is of American origin, but other countries quickly adopted a means so obviously useful in making mountain travel comparatively safe and comfortable for traveler and tourist. The first mountain railway was opened at Mauch Chunk, Pa., in May 1827. It was first used to draw coals from the mines to the Lehigh River, the cars descending by gravity, and being returned by mules. A stationary engine on the summit has taken the place of the

1. The Pennsylvania Special.
2. The Twentieth Century Limited Speeding a Mile in 35 Seconds.

mules, and the train is now used only by tourists. The Mount Washington Railway, in the White Mountains, N. H., opened in 1869, is very steep, and has a grade in places of one foot in three. The track is of three rails, bolted to a heavy timber trestle, the cogwheel which draws the train running up the centre rail. The seats are suspended so as to swing horizontally. The Otis Elevating Railway, in the Catskills, has an incline 7,000 feet in length with a rise of 1,000 feet.

In the Western United States, also, are some celebrated mountain railways, including the road from Manitou to the summit of Pike's Peak, Colo., eight miles long, and ascending 14,146 feet. The aerial railway over the Chilkoot Pass to Lake Linderman, Alaska, completed early in 1898, shortened the time from tidewater to the headwaters of the Yukon River from a month to a day, and greatly reduced the hardships of a journey to the mines.

Switzerland presents some fine examples of mountain railways. The electric railway to the summit of the Jungfrau (13,670 feet), constructed in 1903 and 1904, is a triumph of modern engineering. The greater part of the way is underground, and galleries are cut at each station to allow passengers to obtain views of the magnificent scenery. The average gradient is 17 per cent, the maximum being 25 per cent. The gauge of the track is 39 inches, the weight of the rails is 42 pounds per yard, and these are bonded and cross-bonded. The sleepers are of steel of the usual continental type, and the rails are fixed by means of bolts and clamps. The journey to the top occupies about one hour and forty minutes, which enables the passengers to accustom themselves to the altered conditions of the atmosphere. At the terminus station the passenger may ascend to the summit of the great mountain, with its dazzling shroud of eternal snow, either by a lift 242 feet high, or by a winding staircase on the outside.

Another interesting mountain railway is that which circles Mount Etna in Sicily. Twenty-two miles of cutting had to be made through lava as hard as granite, and the line, which is only 70 miles long, required four years to complete. It passes through a flourishing region and also scenes of former havoc by volcanic eruptions, and is much appreciated by tourists.

Raimond, rā'mònd, C. E. See PARKES, ELIZABETH ROBINS.

Raimondi, rī-mōn'dē, Marco Antonio (MARKANTON), Italian copper-plate engraver: b. Bologna about 1488. He acquired the goldsmith's art in France and was especially successful in niello, but finally gave all his attention to engraving on copper. In 1505 he went to Venice and attracted attention by his copy on metal plate of Dürer's 'Life of the Virgin.' He was later attracted to Rome, where Raphael soon selected him as the engraver of his pictures. After Raphael's death Giulio Romano commissioned him to make plates from 20 of his best paintings, but having reproduced some licentious designs of that artist, Pope Clement VII. or-

dered the plates to be destroyed by the public executioner and Raimondi was cast into prison. He was released through the intercession of the sculptor Bandinelli, and to show his gratitude Raimondi made a copy in line engraving of Bandinelli's 'Martyrdom of Saint Lawrence.' Losing his property in the sack of Rome (1527) he returned to Bologna where all traces of him are lost. The value of his engravings after Raphael lies in the fact that they were executed under that artist's eye, and were many of them copies, not of completed pictures, but of rough draughts and tentative designs, which but for these copper-plate reproductions would have been lost to the world. Being thus brought in intimate relation with the painter's methods, he became the best interpreter of Raphael in black and white, and no engraver has so completely entered into the spirit and power of expression which breathe in the canvases of the greatest Italian painter. His best engravings after Raphael include 'Adam and Eve'; 'God Commands Noah to Build the Ark'; 'The Massacre of the Innocents'; 'Mary with the Dead Christ'; 'The Judgment of Paris'; 'The Three Doctors of the Church.' Consult: Delaborde, 'Marc-Antoine Raimondi' (1887).

Raimund de Sabunde, rī'moond dā sā-boon'dā, scholastic philosopher: b. Barcelona. In 1436 he appears at Toulouse as a teacher of medicine, philosophy, and theology, and he labored especially to reconcile the apparent contradictions between nature or reason and the Bible; an undertaking which led him into the realm of mysticism. In his 'Liber Creaturarum seu Theologiæ Naturalis' he applied this principle so as practically to reconstruct the whole system of Church doctrine. He and his system have been discussed by Matzke (1846); Huttler (1851); and F. Nitzsch in the 'Zeitschrift für historische Theologie' (1859).

Rain, water dropping through the atmosphere. A mass of air in the atmosphere always contains some aqueous vapor, and if this air is cooled below a certain temperature, called the dew-point (which depends on the amount of vapor present), the vapor will condense into drops of water. This cooling may be due to radiation of heat to colder regions, or to mixture with colder masses of air. When air rises in the atmosphere to colder regions, or comes in contact with a cold part of the earth, or passes from equatorial to polar parts of the earth, its moisture tends to condense into rain. In considering the probable rainfall of a place we are concerned with its latitude, its elevation above the sea, its proximity to the sea, the laws affecting its seasonable variations, the prevailing winds, and the configuration of the surrounding surface. Low latitudes have in general a heavy rainfall, because of the greater evaporation in tropical regions, and the consequent formation of rain when the clouds due to evaporation get colder in the higher regions of the atmosphere. Hence also winds blowing from the equator are generally moist, and winds blowing to the equator are generally dry. The presence of forests tends to increase the rainfall (see METEOROLOGY), and the rain further encourages vegetation. The influence of the seasons on rainfall is pretty regular in the tropics. Over the ocean the skies are clear where the trade-winds are blowing steadily, and heavy rain falls by day in the zone

RAIN-BIRDS — RAIN-MAKING

of calms; on land there is a regular alternation of dry and wet seasons. Toward the equator, where there is a considerable interval between the two passages of the sun across the zenith, there are two rainy seasons. In monsoon regions, however, the alternation of dry and wet seasons depends on the winds. Beyond the tropics we have variable winds and variable rainfall. The following table gives recent figures for the mean annual rainfall of a number of stations in various parts of the world:

| | Inches | | Inches |
|--------------------------------|--------|-----------------------------|--------|
| Greytown (Nicaragua) | 260 | Perth (Australia) .. | 32 |
| Freetown (Sierra Leone) | 125.8 | St. John (New Brunswick) .. | 31.75 |

It has been proven that rain has a most cleansing effect on the atmosphere, a five days' rainfall in London, England, having carried off not less than 3,738 tons of solid impurities, including 267 tons of sulphate of ammonia, and 2,000 tons of soot and suspended matters.

Rain-birds, various birds so called because of their observed or supposed connection with rains or the foretelling of wet weather. The cuckoos seem to be most widely credited with foreknowledge of storms, as they are in the habit of calling most noisily at such times. Thus the yellow-billed cuckoo (see Cuckoo) is called "rain-crow" in the Southern and Western States. Further Southwest, and in Mexico and Central America, the name is given to the anis (q.v.); while in the West Indies two or three other cuckoos are so termed. These are familiar species of the genera *Saurothera*, *Hytornis*, and *Piaya*, the last named extending over most of the Andean region. The rainbird of India is a quail (*Coturnix Coromandelica*), which recalls one of the names, "wet-my-lip" of the American eastern quail; and that of the Malay region is one of the broadbills (*Cymborynchus*). In England the green woodpecker

is called "rain-bird"; and in the Orkney Islands one, the loons, especially the red-necked, is known as "rain-geese." The prophetic power of the birds is exaggerated in popular estimation; but probably they do somewhat perceive a coming change of weather, especially of increased moisture, and those, like the above mentioned, which are naturally noisy, do then call more loudly and frequently than usual.

Rain-gauge, or **Pluviometer**, an instrument which measures the depth of the rainfall at any place. In its commonest form it consists of a cylindric vessel closed at the top by a funnel-shaped lid, through a hole in the centre of which the rain falls. A narrow glass tube, rising outside the vessel from near the bottom, shows by the height of the water in it the height of the water in the vessel itself. A very simple rain-gauge consists of a copper funnel, the area of whose opening is exactly 10 square inches. This funnel allows the rain to pass into a bottle, and the quantity of rain caught is ascertained by multiplying the weight in ounces by 0.173, which gives the depth in inches. As a rain-gauge is nearer the ground it is found to indicate a greater rainfall. This is partly due to the cold rain-drops getting larger in falling through the very moist air near the ground, and partly to the greater occurrence of eddies about the gauge at greater heights. Hence, when the rainfall at two places is to be compared, the gauges ought to be similarly situated. A rain-gauge must be placed in as open a position as possible, out of the way of houses, trees, and similar objects.

Rain-making. The subject of rain-making, or bringing rain from the clouds in a season of drought, has in all ages been of the greatest interest to humanity, as lack of rain has caused many famines and the loss of many millions of lives. Attempts have been made to bring rain by appeals to Divine Providence in prayer in Christian countries, while the ignorant heathen practise various forms of fetishism, and even offer up human sacrifices with the same object. Owing to the large extent of arid lands in the United States the question of bringing about rain by scientific processes has engaged attention for many years past. It was noted that forest fires have often been followed by rain, and in 1834 James P. Espy, of Pennsylvania, proposed the building of enormous fires in the regions where rain was desired, to bring about the needed showers. This was regarded as impracticable both in America and in Australia where it was also suggested. That great battles, and sometimes lesser ones, attended by cannonading, were occasionally followed by heavy rainfalls is a historic fact, and this gave origin to the belief that explosions similar to those of artillery might bring about rain in a season of drought. This belief did not apparently take into account the circumstance that important battles are usually fought in temperate regions, with normal rainfall, and where a disturbance of the atmosphere might easily bring a downpour from the skies. It is also averred by the opponents of this theory that the number of battles followed by rain has been comparatively small. In 1891, however, Congress made an appropriation for a series of experiments in Texas, which were conducted by

RAIN-TREE — RAINBOW

Gen. Dyrenforth for the Department of Agriculture. There has been much controversy as to the effect of these experiments which were conducted on the theory of provoking rainfall by concussion caused by explosions, giant powder being the explosive used. Gen. Dyrenforth claimed that the experiments were entirely successful, that the drops sometimes commenced to fall within 12 seconds after the initial explosion, and that "the concussions from explosions exert a marked and practical effect upon the atmospheric conditions, in producing or occasioning rainfall, probably by disturbing the upper currents." On the other hand, Prof. A. H. Hazen, basing his views on the newspaper reports of the experiments, argued that there was no evidence whatever that any rainfall had been produced by the explosions, while W. K. Curtis, M.D., who was with the Dyrenforth party, substantially confirmed Prof. Hazen's view, and declared that rain fell before the experiments had begun. The weight of evidence was generally accepted by the public as supporting the views of Hazen and Curtis, and while the theory that rain frequently follows aerial explosions has not been abandoned, no serious efforts have been made to follow up the experiments of Gen. Dyrenforth. See METEOROLOGY.

Rain-tree, a leguminous tree (*Pithecolobium saman*) of tropical America, now largely planted in India for the shade it furnishes, and because it flourishes in barren salt-impregnated soils, as well as for its sweet pulpy twisted pods, which are greedily eaten by cattle. Another species (*P. dulce*) with edible pods is a native of Mexico, but has been introduced into the Philippine Islands and also into India.

Rainbow. The rainbow is the best known of all optical meteorological phenomena, consisting of a colored arch formed opposite the sun on falling raindrops, and visible whenever the necessary conditions of a passing shower on one side and a clear and not too high sun on the other occur. Two bows are frequently seen, each exhibiting the full spectrum of colors from red to violet; but in the inner or primary bow the red is the outer edge and violet the inner, while in the outer or secondary bow the order is reversed, the red being inside and the violet on the exterior. The colors are always arranged in a definite order, that of the solar spectrum,—namely, red, orange, yellow, green, blue, indigo, and violet, but shade imperceptibly into each other. The cause of this breaking up of the sunlight into its constituent colors is explained in most physical and meteorological text-books, but may be briefly summarized as follows:

For the primary bow (Fig. 1), let PQR represent the section of a raindrop, and SP a ray of light falling on it. The ray enters the drop at P, meets the surface again at R, is reflected to Q, where it leaves the drop in the direction of QE. The ray is refracted or bent on entering the drop at P and again on emerging at Q—the amount of this refraction depending on the acuteness of the angle at which the ray meets the surface. Now it may be shown that there is a particular point P, such that any ray from S striking the surface below P emerges again above Q, and any ray above P also emerges above Q—the former owing to the more acute angle of the reflection, and the latter to the greater refraction on entering and leaving the

drop. The course of two such rays is shown by the dotted lines in Fig. 1. Q is thus a turning-point in the emerging rays, and near it a

FIG. 1.

very large number of rays pass out, and an observer at E sees a bright image of S in the direction EQ. This statement applies to any one color of sunlight; but, as the refrangibility increases from red to violet, the latter is bent more at P and Q, and the line EQ lies at a flatter angle. The observer, therefore, sees the violet rays reflected on drops at a less altitude than those that reflect the red, the other colors being intermediate. The raindrop being spherical, this reflection takes place in all directions, the fixed condition being the radius of the bow, that is the angle between the line from the observer to the bow and that passing from the sun to the observer, or, in other words, the observer's shadow. For red light this angle is $42^{\circ} 39'$, and for violet $40^{\circ} 13'$. If the sun were a luminous point each color would be sharply defined, but as the disk of the sun subtends an angle of about $30'$ each color is broadened to this amount, and they overlap.

Exactly similar reasoning explains the secondary bow (Fig. 2). The light that forms it

FIG. 2.

has been twice reflected, at R and at R'; the point Q lies above P, and rays entering either above or below P all emerge below Q. A glance at the diagram will show that the greater bending of the more refrangible rays makes the line EQ more nearly vertical, and therefore the violet rays form the outer edge and the red the inner of the secondary bow. The radius of the red is $50^{\circ} 5'$, and of the violet $54^{\circ} 0'$. The space between the bows gets no reflected light, but that inside the primary and outside the secondary is faintly illuminated by rays such as are indicated by the dotted lines in Fig. 1 and their equivalents in Fig. 2, which are not shown. These rays "interfere" with each other, and cause alternations of color which appear as spurious bows inside the primary and outside the secondary. They can only be seen with strong sunlight and small drops of rain.

The radius of the primary bow being roughly

RAINBOW FALLS—RAINSFORD

40°, it is evident that it cannot be seen when the sun is at a greater elevation than this, as the highest part of the bow would lie below the horizon. See LIGHT.

Rainbow Falls. See CHELAN, LAKE.

Rainbow Trout, a fresh-water fish (*Salmo irideus*) indigenous to the mountain streams and rivers of the Pacific coast of the United States, but widely introduced into eastern waters. From the eastern brook-trout (*Salvelinus fontinalis*) it may be easily distinguished by its colors and the presence of teeth on the vomer bone; from the related salmon trouts, with some difficulty, by its small mouth, and the number of scales, about 135 in typical examples, along the lateral line. The rainbow trout is exceedingly variable and many distinct forms, which are considered by ichthyologists to be modifications of this species but which have received distinct vernacular names, are found occupying particular streams or watersheds. The complex relations of the various species of trout and salmon to their environment is little understood. From fish-culturists the McCloud River trout (*S. irideus shasta*) has received much attention since 1880. This variety is particularly well adapted for stocking streams and ponds in which the brook-trout no longer thrives owing to the clearing of the forests and the resulting higher temperature and increased muddiness of the water. To supply the great and constant demand for young fish for stocking purposes the Federal Fish Commission maintains several large hatcheries and many States others. Carefully selected breeding fish are kept in specially constructed ponds designed with reference to cleanliness, good circulation, and ease of handling the fish. Spawning occurs during the winter. The ripe females are stripped in the usual way and the eggs mixed with the milt in a pan either with or without water. After a few minutes water is added and they are gently agitated and repeatedly washed to remove the surplus sperm, and, after standing about an hour, are transferred to the hatching trays, which are constructed of galvanized wire. These trays are arranged in troughs with running water in such a way that the young fry fall into the latter as they hatch. As the fry grow and begin to feed they are distributed to other troughs and finally to rearing ponds constructed in a manner to insure cleanliness and an abundance of flowing water. The young are fed on ground liver and are transplanted when several months old. They grow rapidly, but in the East never attain the large size which they do in their native streams. They feed on insect larvae, etc., and may be fed artificially on chopped beef or liver mixed with corn meal. For angling purposes the rainbow is inferior to the brook-trout, but is a fair substitute.

Raines, John, American politician: b. Canandaigua, N. Y., 6 May 1840. He was graduated from the Albany Law School in 1861, and admitted to the bar. He served in the Civil War as captain from 1861 to 1863; then began his law practice. He was a Republican member of the New York Assembly in 1881-2, and again in 1885; of Congress in 1889-93; and of the State Senate in 1886-9, and since 1895. In 1903-4 he was president *pro tem.* of the Senate and chairman of the committee on rules. He is best known as the author of the Raines

Liquor Law (q.v.), and he also framed the State election law.

Raines' Law, so called from State Senator John Raines, who introduced the measure, a law passed in 1896 by the legislature of New York, and since amended in several particulars, but always retaining the essential features of State control of the liquor traffic, and high license for cities, the present full license under the amendments of 1903 being \$1,200 in the old city of New York, and \$800 in the borough of Brooklyn. The law permits hotels to sell to guests on Sunday, and this has led to the establishment of numerous places known as "Raines' Law Hotels," which comply with the strict letter of hotel regulations, but do what is chiefly a liquor saloon business. The law has been very profitable in its operation both for city and State, the city receiving two thirds and the State one third of the net income from licenses. In the year ending 30 April 1903 the net receipts were \$7,991,865.39 in New York city, as against \$1,736,918.43, the last year of the old excise law in all the municipalities which now constitute the city.

Rainier, rā'nēr, Mount, a peak in the State of Washington, belonging to the Cascade Range, 14,520 feet above sea-level and about 10,000 feet above the surrounding land. It is near Puget Sound, east of Tacoma, and it is sometimes called Tacoma. It is of volcanic origin, cone shaped; its crater still sends out volcanic gases, but it is classed with the extinct volcanoes. The eroded slopes indicate there has been no eruption for hundreds of years. The base and the lower slope are covered with forests, but the summit is snow-capped. There are a number of glaciers on the summit. The first ascent of the mountain was made in 1870. In 1897 it was ascended and quite thoroughly explored by a large party. See ROCKY MOUNTAINS.

Rains, George Washington, American military officer: b. Craven County, N. C., 1817; d. Newburgh, N. Y., 21 March 1898. He was graduated from West Point in 1842, served in the engineering corps, was transferred to the artillery, and in 1844-6 was assistant professor of chemistry, mineralogy, and geology at West Point. He served on the staffs of Gens. Scott and Pillar in the Mexican War, and received brevet rank of major, was active in the Seminole War, and in 1856 he resigned from the army and engaged in business. At the outbreak of the Civil War he entered the Confederate service, was commissioned a colonel and placed in charge of the building and equipment of a powder mill at Augusta, Ga., where he remained until the end of the war, receiving promotion to the rank of brigadier-general. In 1867 he became professor of chemistry and pharmacy in the University of Georgia, and was dean of the faculty there till 1884. He was interested in mechanics, and secured several patents on his inventions for improvements for steam-engines. He wrote: 'Steam Portable Engines' (1860); 'Rudimentary Course of Analytical and Applied Chemistry' (1872); 'History of the Confederate Powder Works' (1882); etc.

Rains'ford, William Stephen, American Episcopal clergyman: b. Dublin, Ireland, 30 Oct. 1850. He was graduated from Saint John's College, Cambridge, in 1872, took orders in the

English Church, and in 1873-6 was curate at Saint Giles', Norwich, England. In 1876 he came to the United States and engaged in evangelistic services in New York. He was assistant rector at Saint James Cathedral, Toronto, 1876-83, and in the last named year became rector of Saint George's Church, New York but resigned in 1906. Under his management the work of the parish was greatly extended and many societies and missions were established in connection with it. He is widely known as an earnest, fearless, and eloquent preacher. He has published: 'Sermons Preached in Saint George's'; 'Reasonableness of Faith' (1902); 'A Preacher's Story of His Work' (1904), etc.

Rainy, Robert, Scottish Presbyterian clergyman: b. Glasgow, Scotland, 1 Jan. 1826; d. 22 Dec. 1906. He was educated at the University of Glasgow, held various important pastorates in the Free Church, was professor of church history at New College, Edinburgh, in 1862-1900, and from 1874 was principal there. He published: 'Life of Principal Cunningham' (1871); 'The Bible and Criticism' (1878); 'The Ancient Catholic Church' (1901); etc.

Rainy Lake, Canada, between Lakes Superior and Winnipeg, forms part of the boundary between Canada and the United States. It is about 40 miles long by 15 miles broad, receives the waters of numerous small lakes from the east and northeast, and empties itself by Rainy River, about 90 miles long, into the Lake of the Woods.

Raised Beaches. See BEACHES, RAISED.

Raisin, the commercial name for the dried or cured grape. In Europe the raisin product comes largely from Italy and France, and in the United States almost wholly from California. See RAISIN INDUSTRY, THE.

Raisin Industry, The American, is confined almost wholly to California. The raisin crop comes from the great San Joaquin Valley and from several counties in southern California. The headquarters of the industry are about Fresno. The California raisin grape culture began to be of commercial importance in 1874, when the output was 9,000 boxes, or 180,000 pounds of raisins. The industry advanced "by leaps and bounds" up to 1894, when the crop amounted to 103,000,000 pounds—figures which have never since been exceeded, or even equaled. The markets "broke" under this great output, and the crop sold for less than 2 cents per pound. As a result there was a sharp decline both in the acreage and in the output of raisins during the next four or five years. However, the growers protected themselves and their market by forming, in 1898, a Raisin Growers' Association, which controlled about 90 per cent of the yield. This association still continues to handle the bulk of the raisin crop, and has been quite successful in distributing to the best advantage the large output in the different markets. Last year (1902) the California raisin crop amounted to 100,000,000 pounds. The standard box of raisins weighs 20 pounds, and contains four layers of five pounds each. The raisins are packed and graded into layers, and one, two and three crown loose. The processes of curing, seeding, and packing raisins have been improved from time to time, and to-day

machines do much of the work formerly done by hand. The first great device was a patent seeder, and the latest one is a raisin-packing machine, by which the packages, or cartons, are filled, weighed and sealed.

The leading varieties of grapes used for raisins are: Muscatel, Gordo Blanco, Muscat of Alexandria, and Malaga; for seedless raisins, Sultana and Thompson's Seedless. Grapes are ripe by the middle of August, and the season often lasts into November. The average time of drying and curing a tray of raisins is about three weeks, all depending on the weather. The earliest picked grapes dry in ten days, and the later ones often take four weeks and even more. The method of drying is very simple. The bunches are cut from the vines and placed on shallow trays two feet wide, three feet long, and one inch high, on which the grapes are allowed to sun-dry, being turned from time to time by simply placing an empty tray top side down on the full one, then turning both over, and taking off the top tray. After the raisins are dried they are stored away in the sweat boxes until they are packed and prepared for shipment. Some of the larger growers, in order not to run so much risk in drying on account of rain, and also to enable them to handle the crop fast enough, have curing houses, where the curing is finished after having been partially done outside. The seeding, grading, packing, and shipping have become separate branches. In the season of 1901-2 some 60 plants, most of them located in the Fresno district, were engaged in this part of the work. These establishments furnished employment for 5,000 employees, and the aggregate wages paid out to them each month during the season was nearly \$250,000.

The exports of California raisins first became of sufficient importance to be separately stated in the official reports of the treasury department in the fiscal year ending June, 1892. Raisins were first sent in small quantities to all parts of the world, but the trade has grown quite rapidly. In 1898 the exports amounted to 3,109,639 pounds, and in 1902 to 2,323,274 pounds.

The following figures serve to show how the foreign raisin trade has fallen off, and how California raisins have monopolized the markets of this country:

RAISINS PRODUCED AND IMPORTED.

| Year | Raisins produced Pounds | Raisins imported Pounds |
|------------|-------------------------------|-------------------------------|
| 1885 | 9,400,000 | 53,702,220 |
| 1890 | 38,000,000 | 36,914,330 |
| 1895 | 91,360,000 | 15,921,278 |
| 1898 | 80,631,000 | 6,593,833 |
| 1902 | 100,000,000 | 6,563,302 |

Editor of the 'American Wine Press.'

Raisin River, Battle of. See MONROE, MICH.

Raja, rä'jä, or **Rajah**, a title of hereditary princes of the Hindus. Before the subjugation of the country by the Moguls the various countries of Hindustan were governed by rajas, who belonged to the Kshatriyas or military caste. They were sometimes independent rulers and again feudatory, and the highest title, "Maharaja," was given to those who controlled other sovereigns. The title is now usually merely

honorary and is not confined to any caste, while those retaining some degree of actual authority under the British are now designated "Maharaja." Consult: Foy, 'Die königliche Gewalt nach den altindischen Rechtsbüchern' (1895); Jolly, 'Recht und Sitte' (1896).

Rajamandry, rā-jā-mān'drē, or **Rajamahendri**, India, a town of the Godavari district, Madras, on the east bank of the Godavari (here three miles wide), 30 miles from the sea. Among buildings and institutions are the court-house and judge's residence, churches, mission of the American Evangelical Lutheran Church, provincial college, several schools, museum, dispensary, public garden, and large prison. Pop. 28,500.

Rajmahal, rāj-mā-hāl', India, on an eminence overlooking the Ganges, 170 miles northwest of Calcutta, for many years ranked first among the towns of the Bengal and Bahar provinces. It is now noteworthy only for its palatial ruins, and as a station in an important transit trade. Pop. (1900) 25,000.

Rajon, rā-zhôn, **Paul Adolphe**, French etcher: b. Dijon 1842; d. Auvers 8 June 1888. He was trained at the Ecole des Beaux Arts at Paris, and in 1865 produced his first etching after Meissonnier's 'Rembrandt at Work.' His many subsequent works won for him the leading position among French etchers, and on visiting England in 1872 he found his reputation had preceded him and was commissioned to make an etched copy of John Stuart Mill's portrait by George Frederick Watts, and of Tennyson's portrait by the same painter. He was eminently successful in these and other portrait etchings, but his most ambitious and brilliant work was 'The Emperor Claudius' after Alma Tadema.

Rajputana, rāj-poo-tā'na, India, a western political division, extending from the Jamna and Chambal rivers, west to Sind and Bhawalpur, and comprising the greater part of the Indian Desert. It consists of a number of native states controlled by the British assistant political agencies of Mewar, Jaipur, Marwar, Haraoti, Eastern States Agency, Alwar, and Sirohi; together with the British enclave of Ajmir-Merwara. The total area of the native states is 127,541 English square miles; or including the British district of Ajmir-Merwara 130,252 square miles. The maharajas and rajas are supreme in their own states, and settle disputes among themselves in courts of their own. A great portion of the surface of Rajputana is desert, and part of it wholly destitute of inhabitants, water, and vegetation. The whole of the soil is remarkably saline, containing many salt springs and salt lakes, and much of the well-water is brackish. The rainfall is scanty, and the region frequently suffers from famine. In many places it is covered with the cactus and other prickly shrubs; except in the Aravalli Hills which traverse the region from southwest to northeast, the territory is almost destitute of trees. Where practicable, pastoral and agricultural pursuits occupy the people. Conditions have slightly improved since British enterprise has opened up the country by a transversal line of railroad, with diverging branches, connecting with the rest of the Peninsular railway system. The chief town is Jaipur, other urban

centres are Bikanir, Jodhpur, Bhartpur, Udaipur, and Tonk. While the chiefs are of Rajput origin, the Rajput element is in the minority among the population, which consists chiefly of Hindus, with Mohammedans, Animists, and Jains. Pop. (1891) 11,990,504; (1901) 9,723,301, showing a decrease in the decade of 2,267,203, mainly due to the famine of 1899-1900.

Rajputs, rāj-poots', a people of India, giving their name to Rajputana (q.v.), and said to be a branch of the Kshatriyas, one of the four great castes into which the Hindus were originally divided. They are essentially a military people, and many of their institutions bear a strong resemblance to the feudal customs which prevailed in Europe in the Middle Ages. They are celebrated for their chivalrous spirit in marked contrast to the usual effeminacy and duplicity of many of the Oriental nations. The practice of female infanticide, however, at one time was prevalent among them, until suppressed by British influence; the profuse use of opium has likewise in many cases produced a lamentable deterioration in their physical and moral state. Notwithstanding these drawbacks the Rajput character contains much that is noble and generous. The Rajputs became first connected with the British government under the governorship of the Marquis of Wellesley, in the beginning of the 19th century. Besides Rajputana, the Rajputs are numerous in Sind and Guzerat.

Rājshāhi, rāj-shā'hē, India, a division or commissionership of Bengal, extending from the Ganges to Sikkim and Bhutan. Area, 17,351 square miles; pop. (1901) 8,489,788. The district of Rājshāhi, forming part of the division, has an area of 2,330 square miles; a population (1901) of 1,313,336. The capital of the division and district is Rāmpur Beaulah.

Rákóczy, rākôt-sē, a Transylvanian princely family now extinct in the male line. They were for some time rulers of the principality of Siebenbürgen, or Transylvania, and by a rigorous maintenance of the civil and religious rights of the inhabitants made their influence over their subjects such as to render them formidable to the power of the royal house of Austria. The first prince of the name was SIGISMUND RÁKÓCZY, who obtained the government in 1606, but abdicated in favor of Gabriel Bathori in 1608. His son, GEORGE RÁKÓCZY (b. 1591; d. 24 Oct. 1648), assumed the sovereignty in 1629 and regained for his subjects many lost privileges. He was succeeded by his son, GEORGE II. (b. 1615; d. 8 July 1676), who attempted an invasion of Poland, was defeated and forced to abdicate, but regained his authority. He died after having been again forced to resign. His son, Francis I., never reigned, but was implicated in various political complications and the last of the family to hold sovereign power was his grandson, Francis II. (q.v.).

Rákóczy, Francis II., Transylvanian prince: b. 27 March 1676; d. Rodosto, Turkey, 8 April 1735. His attempt to free his country from Austrian rule resulted in his being sentenced to death for high treason, but he contrived to escape, rallied the Hungarians to his support and was proclaimed protector. The alliance of certain of the Hungarian states with Austria afterward caused his defeat and he resigned his

estates and went to Turkey. He wrote: '*Mémoires sur les Révolutions de Hongrie*' (1738).

Rakoczy March, the name of a Hungarian military air by an unknown composer of the 17th century, said to have been the favorite march of Francis Rakoczy II. of Transylvania. See NATIONAL HYMNS.

Rale, *rál* (spelled also incorrectly, *RASLE*, *RASLES*, and *RALLE*), **Sebastien**, French Jesuit missionary in North America: b. Franche-Comté 1657; d. Norridgewock, Maine, 12 Aug. 1724. In 1675 he became a Jesuit novice at Dôle, in 1677-84 was an instructor at Carpentras and Nîmes, and in 1689 was sent to the American missions. For two years he was among the Abenakis near the mouth of the Chaudière in the mission of Saint Francis. Then he passed two years among the Illinois, and finally was placed in charge of the Abenakis of Kennebec. He was believed by the English to be the cause of their difficulties with the Abenakis, and was accused of instigating attacks on the settlements. This is inferred by pro-English historians from a letter to Rale from Vaudreuil, governor at Quebec, expressing satisfaction at Rale's success in uniting the savages against the English, and agreeing to furnish military assistance, should it be required. This communication, dated 25 Sept. 1721, was among papers obtained by the expedition sent out from Boston under Colonel Westbrook to seize Rale in 1721, and is now preserved in the archives of Massachusetts. Among these papers, also, was Rale's dictionary of Abenaki, now in the Harvard library and printed in 1833, in the memoirs of the American Academy of Arts and Sciences, See DUMMER'S WAR.

Raleigh, Sir Walter, English military and naval commander, and author: b. Hayes Barton, a farmstead in the parish of East Budleigh, Devonshire, about 1552; beheaded, London, 29 Oct. 1618. He was the son of Walter Raleigh by his third wife, Katharine, daughter of Sir Philip Champernowne of Modbury, and widow of Otho Gilbert of Compton. Raleigh was educated at Oriel College, Oxford; served with the Huguenot army in France in 1569; remained there for five years or more; and, with his half-brother, Sir Humphrey Gilbert, engaged in voyages of "discovery"—and piracy—against the Spaniards in the West Indies. In 1579, he established himself at court in the friendship of men of influence—Leicester, Oxford, Sidney, Walsingham; he served with distinction in Ireland (1580-81); and then, returning to court in December of the latter year, he won, and for some years retained, the high favor of Elizabeth. Through her successive grants of monopolies and estates, he became one of the wealthiest of her courtiers. In 1584 he was knighted; in 1585 he was appointed warden of the stannaries (*i. e.* of the mines of Devon and Cornwall), lord lieutenant of the latter county, and vice-admiral of both; and in 1585-6 he was M.P. for Devon. He was also captain of the queen's guard.

From this period while Raleigh was the

favorite of Elizabeth dates his chief connection with the exploration and settlement of North America. In 1584, '85, '86, '87, and '89, he sent expeditions to Virginia; but as the Queen forbade his personal participation, his efforts to colonize were unsuccessful. Raleigh's services against the Spanish Armada, 1588, were not conspicuous. He assisted in organizing the land forces; but there is no proof that he took any part in the sea-fighting. In 1591 and 1592, he was prominent in the preparation of squadrons for service against Spain; but was recalled from the later expedition because of the Queen's anger at Raleigh's intrigue with one of her maids of honor, Elizabeth Throgmorton. He was soon set at liberty, and his marriage to Elizabeth Throgmorton followed. Not until 1597, however, did Raleigh regain the Queen's favor.

Meanwhile he was free to explore America in person. His objective point was Manoa, a city supposedly situated in South America and possessed of untold wealth. In 1595, with a fleet of five vessels, he captured the town of San Josef, Trinidad, and explored the Orinoco for 400 miles. He did not find Manoa; but his brilliant service in the English attack upon Cadiz (June 1596), and as commander at the taking of Fayal (1597), completed his restoration to favor. In 1597 he was made M.P. for Dorset; in 1601, for Cornwall. In 1600 he was appointed governor of Jersey.

The death of Elizabeth, however, occasioned a change in Raleigh's fortunes. Raleigh's enemies had made James believe that Raleigh was opposed to his accession. James immediately deprived him of all offices, and on 17 July 1603, committed him to the tower. On November 17, he was tried for treason. According to modern rules the evidence was insufficient; but Raleigh was declared guilty and was sentenced to be executed on 11 December.

On 10 December, however, he was reprieved and committed to the tower. Here for 13 years he lived in tolerable comfort with his wife, son, and personal servants. He devoted himself to study and to scientific experiments, and, at the request of Prince Henry, began his chief literary work, the 'History of the World.' At length, in March 1616, on his promise to guide an expedition to a gold mine in America, Raleigh was released. The Spanish ambassador, fearing an invasion of Spanish possessions or an attack on the Mexican plate-fleet, protested. The king, however, warning Raleigh that either act would be punishable by death, allowed him to proceed. Raleigh ignored the warning, captured San Tomás, and, failing to reach the mine, was kept from attacking the plate-fleet only by the refusal of his followers. On Raleigh's return to England, Gondomar, the Spanish ambassador, demanded his immediate execution. Raleigh's admissions and perjuries left the king's commissioners no choice. On 28 October, the Justices of the King's Bench ordered Raleigh's execution under the suspended sentence of 1603. He was executed in the Old Palace Yard, 29 Oct. 1618.

Of Raleigh's poetry, so highly praised by his

contemporaries, but little was published during his life, and much is probably lost. Many poems once attributed to him are now attributed to others. The poems certainly his have been collected by Dr. Hannah, 1885. Of Raleigh's prose works, the most important is his 'History of the World' (1614).

Bibliography.—The chief lives of Raleigh are those of William Oldys (1736); Thomas Birch (1751); Arthur Cayley (1805); Patrick Fraser-Tytler (1833); Edward Edwards (1868); J. A. St. John (1868); and Mr. William Stebbing (1891). That by Mr. Stebbing is the best. There is also a popular sketch by Mr. Edmund Gosse (1886). Consult also Mr. S. R. Gardiner's 'History of England,' and the publications of the Hist. MSS. Comm., and, concerning Raleigh's literary work, the introduction to Dr. Hannah's edition of his 'Poems' (1885), the bibliographies of Dr. Brushfield, and his 'Sir Walter Raleigh and His History of the World' (1887).

ARTHUR H. NASON,

Instructor in English, New York University.

Raleigh, Walter, English author and educator. He was educated at University College, London, and King's College, Cambridge, and was for many years professor of modern literature at University College, Liverpool. Since 1900 he has occupied the chair of English language and literature at Glasgow University. He has published: 'The English Novel' (1894); 'Robert Louis Stevenson' (1895); 'Style' (1897); 'Milton' (1900); 'Wordsworth' (1903); etc.

Raleigh, N. C., city, capital of the State, county-seat of Wake County; in lat. 35° 47' N., lon. 78° 48' W.; on the Southern and the Seaboard Air Line R.R.'s; about 28 miles southeast of Durham, 148 miles northwest of Wilmington, and 60 miles northeast of Pinehurst.

Topography.—Raleigh occupies an elevation of over 300 feet. It is just northeast of the geographical centre of the State, in the upper valley of the Neuse River, which flows southeast to Pamlico Sound. The city, platted around a beautiful park of 10 acres, which is called Union Square, is divided into four sections by four broad streets which extend from this centre. The magnificent oak trees in Union Square give Raleigh the popular name of "The City of Oaks."

Manufacturing.—In 1900 the manufacturing interests of Raleigh represented an invested capital of \$1,611,000, with products valued at \$2,204,000. Cotton and tobacco products are the leading articles of commerce. The largest manufacturing establishments are flour mills, phosphate works, foundries, machine shops, car shops, wood-working factories, ice factories, cotton mills, and cottonseed-oil mills. Other manufactures are underclothing, hosiery, cigars, carriages, and agricultural implements.

Buildings and Cemeteries.—The State Capitol, a substantial granite structure, stands in Union Square; nearby are the Supreme Court building, the State Library, State Geological Museum, Raney Library, Governor's mansion, U. S. Government post-office and court-house. Other prominent public buildings are the county court-house, State insane asylum, State peniten-

tiary, State institutions for the blind, one for white and one for colored, State Institute for the Deaf and Dumb, Old Ladies' Home, and Rex Hospital. There are here National and Confederate cemeteries. The National Cemetery contains 1,207 graves, 572 of which are unknown dead.

Education.—The educational institutions are the Peace Institute (Presbyterian), Saint Mary's (P. E.), and the Baptist Female University, for young women; Raleigh Male Academy, for boys. The State College of Agricultural and Mechanic Arts, opened in 1889, has 15 buildings, and accommodations for 600 students. Other schools are King's Business College; the Shaw University (Baptist) and Saint Augustine's School (P. E.) are for boys and girls. Several State educational institutions have been mentioned. There are graded and normal schools for white and colored pupils. A large summer school for white teachers is held here each year. Not far distant from the city are the State University and the Wake Forest College (Baptist). The Supreme Court Library contains 14,000 volumes, the State Library 35,000 volumes, and the Olivia Raney public library 8,000 volumes. All the religious denominations have handsome churches for both races. There are two orphanages, one under the auspices of the Methodist Church, the other in charge of the Roman Catholic Church. There are three daily and ten weekly newspapers.

Banks and Finances.—There are two national banks, one state bank, two savings banks, and one trust company. The five banks and the trust company have a combined capital of \$555,000 and deposits amounting to \$2,541,610. The assessed property valuation, in 1903, was \$6,000,000. There are excellent fire and police departments, and all municipal improvements are provided for by a regular tax.

Government.—The city is governed under a charter of 1899 which provides for a mayor and common council elected every two years. The administrative officials are chosen by the mayor and council, except the tax collector and city clerk who are elected by the people.

History.—The site of the present city was selected in 1792 by the legislature, for the location of the State capital. In the same year the city was founded and named in honor of Walter Raleigh (q.v.). In 1794 the legislature held its first session in Raleigh. The city was incorporated in 1795, and in 1803 was re-incorporated. The city was occupied by General Sherman part of 1865. Pop. (1880) 9,265; (1890) 12,678; (1900) 13,643; (1904) est. 15,000. Consult Battle, 'The Early History of Raleigh.'

GEORGE ALLEN,

Sec. Chamber of Commerce, Raleigh, N. C.

Râles, sounds heard in the respiratory passages, due to certain modifications in the normal structure of the bronchi or alveoli, or both. Sounds that originate in the pleural cavity are distinguished as friction sounds. Râles are new sounds, not common to healthy lungs, and are created either in the bronchi, bronchioles, air-vesicles, or pathological cavities. They are due to a number of causes, the most frequent of which are (1) the passage of air through narrowed bronchi, such narrowing being the result of inflammation of the mucous membrane or of muscular spasm, and (2) the passage of air

SIR WALTER RALEIGH.

through or by a certain amount of fluid, either mucus, pus, blood-serum, or combinations of these. Râles of the first type are dry; those of the second are called wet. The dry râles are usually musical, and on placing the ear to the chest, where they are present, one hears either high-pitched whistling sounds, sibilant râles, or low-pitched, blowing, or sonorous râles, depending on the source of the sound, whether the finer or larger bronchi. Both types may commingle. Such râles are common in asthma, in the chronic bronchitis of emphysema, and in the early stages of a bronchitis, before the exudation of mucus has begun. The moist râles are usually of two kinds: (1) very fine, or subcrepitant râles, resembling in sound the rubbing of a lock of hair between the fingers, and (2) larger mucous râles. The former are common in various types of disease in which the air-vesicles are involved, broncho-pneumonia, lobar pneumonia, tuberculous pneumonia, etc. They are due to congestion and the pouring out of blood-serum into the area. The moist mucous râles are present in bronchitis. They occur in the larger bronchi, or in cavities, and resemble the bubbling and gurgling sounds of water in a pipe. It requires the trained ear of the physician to distinguish between the different varieties, and much experience to be able to prejudge the significance of the râles after they are heard.

Ralph, James, American author: b. Philadelphia, Pa., about 1698; d. Chiswick, Surrey, England, 24 Jan. 1762. He was a clerk to a Philadelphia conveyancer, and in 1724 went to England with Benjamin Franklin, who praises him as "ingenious" and "extremely eloquent." As an actor, editor, and newspaper writer he was not successful. He then became a teacher in Berkshire, and was welcomed as an adherent of the Prince of Wales' party, which he supported by pamphlet, poem, and newspaper contribution. Afterwards brought into silence, he received a pension on the accession of George III. Pope ridicules "a thing of his, entitled 'Night,' a poem," in the lines of the 'Dunciad,'

"Silence ye wolves! while Ralph to Cynthia howls,
And makes night hideous — Answer him, ye Owls!"

Franklin pathetically complains that he "did his best to dissuade Ralph from attempting to become a poet"; but apparently Pope was more effective. Ralph's 'History of England during the Reigns of King William, Queen Anne, and George I.' (1744) is valuable for the information it contains.

Ralph, Julian, American author: b. New York 27 May 1853; d. there 20 Jan. 1903. At 13 he began newspaper work as typesetter and later engaged as reporter at Red Bank, N. J. From here he removed to Webster, Mass., to edit *The Times* of that place, and thence to New York, where he came into prominence in reporting the Beecher trial in 1875. He at once engaged with the New York *Sun* and held a position on its staff for 20 years. He was in the East during the Chinese-Japanese war in 1894 reporting that struggle and traveling in many parts of Asia. Returning to London he joined the foreign staff of the New York *Journal* and reported the Turkish-Greek war, Queen Victoria's Diamond Jubilee in 1897, and the crowning of the Czar of Russia. The outbreak of the Boer war found him again a field correspondent,

attached to the commands of Lords Roberts and Methuen. He returned to America in 1902 and continued his work of special correspondent up to the time of his death. He had a wide knowledge of affairs and a picturesque and vivid style. Some of his books are: 'On Canada's Frontier'; 'Our Great West'; 'Chicago and the World's Fair'; 'People We Pass'; 'Alone in China'; 'An Angel in the Web'; 'At Pretoria'; 'War's Brighter Side.'

Ralph Iron. See SCHREINER, OLIVE.

Ralph Roister Doister, a play by Nicholas Udall. It was the first English comedy, although not printed until 1556, and probably written about 1540. At this time its author was head-master of Eton, and the comedy was written for the schoolboys, whose custom it was to act a Latin play at the Christmas season. An English play was an innovation, but 'Ralph Roister Doister' was very successful. It follows Terence and Plautus, Ralph, "a swaggering simpleton, a feeble, conceited fop of the days of Henry VIII.," having his prototype in the 'Miles Gloriosus.' It is in riming couplets, interspersed with songs. In very recent years it has been produced at Tufts College, Medford, Mass.

Ralston, râl'stôn, William Ralston Shedden, English Russian scholar: b. London 4 April 1828; d. there 6 Aug. 1889. He was the son of W. P. Ralston Shedden and educated at Cambridge. During the period of his college years his father entered upon a litigation to obtain possession of some Ayrshire property and in this effort dissipated his whole fortune. The name of Shedden becoming somewhat notorious in connection with the suit, the son adopted the additional surname of Ralston; and obtained a post at the British Museum in 1853. He gave his attention to the study of Russian, a language then little known. He published 'Kriloff and His Fables' (1868), a translation of Turguénieff's 'Liza' (1869); 'Songs of the Russian People' (1872), and 'Russian Folk Tales' (1873). He made several journeys to Russia and became the life-long friend of Turguénieff, and was also made a corresponding member of the Imperial Academy of Sciences of Saint Petersburg. He projected an exhaustive history of Russia, but did not publish it. In 1874, however, he published his Oxford Tylorian lectures, 'Early Russian History.'

Ram, Thomas, English bishop: b. Windsor 1564; d. Dublin 24 Nov. 1634. He was educated at Eton and Cambridge, and in 1599 accompanied Essex to Ireland, and in the following year was made dean of Cork. On 2 May 1605 he was consecrated bishop of the united sees of Ferns and Leighlin. Ram was a careful bishop, constantly resident, and did what he could to maintain schools, but the recusant clergy excommunicated all who used them. He was one of the twelve bishops who, 26 Nov. 1626, signed a protest against tolerating popery.

Ram, Battering. See BATTERING-RAM.

Ram, Hydraulic. See HYDRAULICS.

Râma, rā'ma, in Hindu mythology, the name common to a personage appearing as three incarnations of Vishnu (q.v.), all great warriors of surpassing beauty. These three forms are distinguished as Bala Râmā or Balaram, Para-

surama or Parasram, and Rāmā Chandra or Dasrat Rāmā. Rāmā first appeared in the sixth incarnation, and his deeds are celebrated in a poem called the 'Rāmāyana,' the best great epic poem of ancient India. In this poem all three of the heroes are celebrated, but the last-named, or Rāmā Chandra, has his life and deeds detailed at greater length than the others. The story tells how Sita, his wife, was carried away to Ceylon by the king of demons, one Ravana, and how Rāmā rescued his wife, bridging the water between Ceylon and India by the aid of an army of monkeys. He slew the demons and became a great hero. The Rāmāyana is often likened to the 'Iliad,' to which it bears great resemblance.

Ramadan, rā-mā-dān' or rām-a-dān', the ninth month in the Mohammedan calendar, has 30 days. Since the Mohammedan year is a lunar one, Ramadan comes at all the seasons, being eleven days earlier each year. In about 33 years the month has made a complete cycle of the year. Ramadan is important chiefly because it is supposed to be the month in which Mohammed received his divine revelation and is therefore made a month of solemn observance among the faithful. During the 30 days the true believer abstains, between dawn and sunset, from all eating, drinking, smoking; bathing and all other delights of the body are likewise forbidden. The more devout of the Mohammedans remain behind closed blinds during the day and devote themselves to prayer and to reading the Koran, and particularly Sura, in the second book of which are found the references to the fast of Ramadan. There are special prayers, 20 in number, which during this month are added to the usual evening prayers, repeated at dusk by the true believer. Ramadan is also the month in which the Turkish Government usually takes occasion to institute reforms, or to promise to institute them, apparently to curtail the national expenses and lighten the tax burden, and generally to undertake those measures that tend to popularize the government with its subjects.

The rigid fast enjoined by the Koran is not required of those who are unable, because of physical reasons, to withstand it. Thus mothers with young babies, and those expecting to become such, infirm old people, people weakened by illness, and others in like circumstances, are excused in whole or in part. In some instances, as is the case with soldiers on active duty, the remission is conditional upon a future fast of similar length and severity.

The fast of Ramadan terminates each day with nightfall, and as the Mohammedan keeps the letter rather than the spirit of the law of the Koran, the nights of this month are filled with feasting, the more joyous because of the abstinence during the day. These repasts often become wild revels, or even flagrant debauches, which last until daylight, when the gluttonous participants once more partake themselves to fasting and prayer. Following the fast of Ramadan for three days there is celebrated the feast of the *Lesser Beiram*, during which all labor ceases and the Mohammedans give themselves to all sorts of table enjoyments.

Rāmāyana, rā-mā'ya-na. See SANSKRIT LANGUAGE AND LITERATURE.

Ram baud, rān-bō, Alfred Nicholas, French historian and litterateur: b. Besançon 2 July 1842. He was educated at the Ecole Normale;

in 1871 became professor of history at Caen and in 1875 was transferred to the same post at Nancy. In 1879 he became secretary to the Ministry of Public Instruction, and in 1881 was nominated to a position in the Normal School at Caen and shortly afterward made professor of modern history at Paris. From 1896 to 1898 he was minister of public instruction in the Méline Cabinet. His chief works are 'La Russie Epique' (1876); 'Histoire de la Russie' (1878); 'Histoire de la Civilisation Française' (1887); 'Histoire de la Civilisation Contemporaine en France' (1888); in collaboration with M. Lavissee, 'Histoire Generale de la France du IVe Siècle à nos Jours' (1892).

Ramberg, rām'bërg, Arthur, BARON, German painter: b. Vienna 4 Sept. 1819; d. Munich 5 Feb. 1875. He studied art at Hanover and early made a tour in Italy, Hungary, and Styria. In 1840 he attended the university at Prague, while at the same time uniting the pursuit of art with his other studies. In 1842 he became a pupil at the Art Academy of Dresden under J. Hübner, and among other early pictures produced his 'Wedding of Dwarfs' after Goethe; and 'The Emperor Henry I. on His Hungarian Campaign.' In 1850 he went to Munich and executed a series of genres illustrating the works of Schiller. In 1860 he was appointed professor to the Art School in Weimar, and six years later took a similar position in the academy of Munich. His subsequent productions include 'The Court of Frederick II. in Palermo'; and, among his genres, most notable are his 'Hermann und Dorothea' after Goethe; and 'Luise,' after the poem of J. H. Voss, which latter was much admired for its brilliancy in design and execution. He also frescoed the walls of Luther's chamber at Wartburg; and for the Grand Duchess of Saxe-Weimar illustrated the tale of the 'King of the Frogs.'

Ramberg, rām'bërg, Johann Heinrich, German artist: b. Hanover 1763; d. there 6 July 1840. He first showed his talent by drawings of scenes in the Harz Mountains. These became known to George III., king of England, his sovereign, as Elector of Hanover, who induced him to go to London, where he provided for him. He remained there nine years, and perfected himself under Reynolds. Murphy, Bartolozzi, and other engravers of the first rank in England, engraved drawings of his. In 1788 the king sent him to Italy, whence he returned to Hanover, where he was appointed painter to the court. Few painters and designers have produced so many works as he; but this rapidity prevented the full development of his talent. He distinguished himself particularly in humorous drawings; as in his illustrations to 'Reineke Fuchs' and 'Eulenspiegel.' The drawings in the magnificent edition of Wieland's works are all by him; some he etched himself.

Rambler, The, a semi-weekly periodical after the model of Addison's 'Spectator,' published in London by Dr. Samuel Johnson 1750-52, and, like its prototype, of much influence upon English life in the 18th century.

Ramboo'tan, the fruit of the tree *Nephelium lappaceum*, of the order *Sapindaceæ*, much prized in the Malayan Archipelago. It is about the size of a pigeon's egg, of a red color, rich and of a pleasant acid taste. The fruits litchi

and longan (see **LITCHI**) are obtained from other trees of this genus.

Rambouillet, răn-boo-yă, **Catherine** (DE VIVONNE), MARQUISE DE, French social leader: b. Rome 1588; d. Paris 2 Dec. 1665. She is worthy of remark as the founder of the Hôtel de Rambouillet, whose hospitality was extended to the learning and wit of Paris, and which became a literary and political centre. This salon was developed in opposition to the French court circle, whose vulgar and barbarous manners and speech it strove to offset by elegance and refinement in both, and it soon became the rendezvous of celebrity and wit. Among the critics, poets, and scholars who resorted thither were Malherbe, Corneille, Chapelain, Scarron, Saint-Evremond, La Rochefoucauld, Mme. de Sévigné, Henry IV. and Louis XIII. were quite indifferent to letters, and in default of royal patronage the Hôtel assumed the role of arbiter in matters literary. Imitators perverted the original characteristics of the group into pedantry and affectation and occasioned the historic satires of the great Molière in 'Les Précieuses Ridicules' and 'Les Femmes Savantes.' The Hôtel did much to add to the precision and finish of the language and the establishment of good taste; and it was unfortunate that through the playwright its name took on the nature of a derisive epithet. Consult: Röderer, 'Mémoire pour servir à l'Histoire de la Société Polie en France pendant le Dix-septième Siècle' (1834); Brunetière, 'Nouvelles Etudes Critiques' (2d ed. 1886); Vincent, 'The Hôtel de Rambouillet' (1900).

Rambouillet, a breed of sheep (q.v.).

Rameau, Jean Phillippe, zhôn fê-lêp rā-mô, French musical composer and theorist: b. Dijon 25 Sept. 1683; d. Paris 12 Sept. 1764. Having early acquired some skill in music he joined a company of performers, by whom when he was 18 a composition of his was represented at Avignon. He studied sacred music under Marchand at Paris; was appointed organist in Clermont cathedral, and in 1722 made his reputation as a musical theorist by publishing 'Traité de l'Harmonie.' Four years after appeared his 'Nouveau Système de Musique Théorique,' which was followed by his 'Génération Harmonique.' His greatest claim to musical reputation is based upon his dramatic compositions, of which 'Hippolyte et Aricie' appeared in 1732 and was followed by 22 works of grand opera, of which the most notable is 'Castor and Pollux' (1737). In 1750 he published his 'Dissertation sur le Principe de l'Harmonie,' in which he reduces harmony to one single principle—the fundamental bass, on which he proves all the rest to depend. This work procured him an invitation from the court to superintend the opera at Paris. Louis XV. granted him a patent of nobility, and the order of Saint Michael, and in 1776 a statue was raised to him in his native city. Consult: Pougin, 'Rameau, Essai sur sa Vie et ses Œuvres' (1876).

Ramée, rā-mă', Louise de la. See OUIDA.

Ramée, Pierre, pē-ār rā-mā (Latinized, PETRUS RAMUS), French humanist and mathematician: b. Cuth, near Soissons, 1515; d. Paris 26 Aug. 1572. He went to Paris about 1523 when he was but eight years old, and became lackey to a rich student in the College of

Navarre, but devoted to self-improvement all the time he could spare. After attending a course of philosophy he was admitted to the degree of M. A., on which occasion he questioned the infallibility of Aristotle. His 'Institutionum Dialecticarum Libri III' (1543), and 'Animadversionum in Dialecticam Aristotelis Libri XX' raised a storm against him in the university; their publication was prohibited, and extant copies ordered to be burned before the Royal College of Cambrai. Having obtained the patronage of the Cardinal De Lorraine, the prohibition of lecturing imposed in 1543 was withdrawn in 1547, and in 1551 he was appointed professor of rhetoric and philosophy in the College Royal at Paris. His spirit of free inquiry ultimately led him to become a Protestant, and he was obliged to flee from Paris, but he unfortunately returned in 1571 and was killed in the massacre of Saint Bartholomew's. His works, relating to grammar, logic, mathematics, etc., are numerous.

His doctrines were widely diffused. France, England, and particularly Scotland, were full of Ramists. His logic was introduced into the University of Glasgow and in the German universities. Consult: Waddington, 'Ramus, sa Vie, see Ecrits et ses Opinions' (1855); Desmazes, 'Ramus' (1864); Lobstein, 'P. Remus als Theolog' (1878); Voigt, 'Ueber den Ramismus der Universität Leipzig' (1888); Owen, 'Skeptics of the French Revolution' (1893).

Ramenghi, rā mēng'gē, Bartolomeo. See BAGNACAVALLLO.

Rameses, rām'ē-sēz, or Ramses (in Egyptian "the Child of the Sun"), the name of several Egyptian kings, especially of the 19th and 20th dynasties, of which the most notable are:

Rameses II. (Gr. Sesostris), son of Sethos. He was the third king of the 19th dynasty, and reigned 1300–1280 B.C. He made a campaign against Syria and advanced victoriously as far as Berytus (Beirut), on the Phœnician coast of the Mediterranean. He next extended Egyptian dominion over Ethiopia, and a part of Arabia and began the cutting of a canal between the Mediterranean and Red seas. But the great event of his reign was his war with the Khita, supposed to be the Hittites. He defeated a confederation, among whom the Khita were the chief, in a great battle near the Kadeshon (Orontes) in Syria, and subsequently took Jerusalem and other places. He fortified the east of Egypt by erecting a great wall from Pelusium to Heliopolis and Tanis. In his reign Thebes rose to great magnificence. Here he erected the splendid temple known as the Rameseum, with a sitting statue of himself more than 60 feet high. He is the king who oppressed the Hebrews, and the father of Menephthah, under whom the exodus took place. He had 111 sons and 59 daughters, and we have more records and statues of him than of any other Pharaoh. His mummy was discovered near Thebes in 1881 and in 1886 placed in the Egyptian Museum at Cairo.

Rameses III., the Rhampsinitus of Herodotus, belonged to the 20th dynasty, and was also a king of note, some of whose achievements seem to have been ascribed to Sesostris. He reigned 1180–1150 B.C., during which period he had to withstand many invasions of the surrounding nations, but was uniformly successful

in war, and active in great undertakings in time of peace. At Medinet-Abu he built a magnificent temple in memory of his warlike achievements in Nubia and Syria. The mummy of Rameses III. was found in 1886. Nine other kings of the name of Rameses are mentioned as having belonged to the 20th dynasty (1150-1050).

Rameses, a city of Egypt, in the district of the same name, supposed to be the same as Raameses, one of the treasure-cities built for Pharaoh by the children of Israel during their bondage in Egypt. It was from this point that the Israelites set out in their exodus from Egypt; and its geographical position is therefore of great interest as determining their route toward the Red Sea. The district or "land" of Rameses has been identified by some with Goshen, or a part of Goshen. As for the city, some have supposed it to be in the neighborhood of On or Heliopolis; others somewhere near Old Cairo, on the opposite side of the Nile from ancient Memphis; Dr. Robinson placed it in the valley of Wady Toumilât, toward the east end of that valley, in the line of the fresh-water canal to Ismailia; and Dr. Lepsius thought he had found its site at Tell-el-Maskhuta, in that region. This site, however, has been identified by Naville with Pithom. It is argued in favor of the conjecture which places it in the neighborhood of Memphis, that Rameses must have been near the capital or residence of Pharaoh at the time of the exodus, and as this was Memphis, Rameses must therefore have been near this city. But though Memphis was the ancient capital, it does not follow that the Egyptian king invariably resided there. Tanis or Zoan was also a royal residence, and Brugsch identifies Rameses with it, an identification which suits the biblical narrative quite well. Upon the name of the city is based the theory which identifies Rameses II. with the Pharaoh of the oppression.

Ramesseum, ră-m-ēs-sē'ūm, a temple of ancient Egypt, on the western bank of the Nile, situated opposite Thebes, and near the modern village of El-Kurneh. Its ruins constitute one of the most interesting group of ancient Egyptian remains, owing to the rich mural sculptures of great historical value which are there preserved. The principal features of the temple were two great courts about 140 feet long by 180 feet wide, entered through a propylon 225 feet wide. The front court contains the fragments of a gigantic statue of Rameses II. carved from a single block of granite and estimated to have weighed, when entire, more than 850 tons. The statue was 60 feet high and the monarch was represented as seated on his throne. The columns in both courts are among the most beautiful specimens of Egyptian architecture. On the wall of the second court is a great series of sculptures depicting a battle between Rameses II. and the Hittites, in which the king is shown as victoriously pursuing the enemy's forces. Opening on the second court is a beautiful hall of pillars, the walls of which are adorned with battle scenes and religious subjects. A smaller chamber adjacent to the hall of pillars is notable for its astronomical ceiling. The temple was described by Diodorus Siculus under the name of the Tomb of Osymandyas. It is sometimes called the Memnonium.

Rameswaram, ră-mēs'wa-rām, a low sandy island between the southern extremity of

India and Ceylon, and between the Gulf of Manaar and Palk Strait, about 14 miles long and 5 wide. It is one of the islands that form the chain known as Adam's Bridge, and contains a famous Hindu temple of Dravidian architecture, which attracts many pilgrims from all parts of India. The port of the island is Pambam; it also contains a small town called Rameswaram. There is a passage for ships of moderate size between this island and the continent. Pop. 17,854.

Ram'ie, Rhea, or China Grass, *Bahmeria tenacissima* and *B. nivea*. Shrubs, five to eight feet high, producing in the bark of their stalks or stems a bast fibre. Technically ramie and rhea are derived from *tenacissima* and China grass from *nivea*. This distinction has never been regarded, however, in the economic literature of the subject, the term ramie being commonly used to designate all *bahmeria* fibre, China grass being either a synonym or the trade name of the Chinese fibre as imported. In the statements which follow, therefore, ramie and China grass may be considered as synonymous terms, referring to the fibres of both species, as they are practically identical from the standpoint of commercial utility, and as regards culture, preparation and manufacture.

The fibre is strong and durable, is least affected by moisture of all fibres, and takes first rank as a textile substance. It is adapted to the widest range of uses of any known textile. It has been made into stuff goods for men's wear, ladies' dress goods, upholstery, curtains, laces, and embroideries. The pile of velvets and plushes, stockings, underclothing and knit goods, table damask, napkins, handkerchiefs, shirtings, sheetings, sail duck, carpets, cordage, fishing nets, and yarns and thread of all descriptions, and it makes a superior bank-note paper. It is also used to adulterate silk, and for imitation silk goods. The plant has been the subject of experiment in nearly every country in the world, and probably millions of dollars have been spent or wasted, in attempts to exploit the industry, or in the construction of machines to extract the fibre. Yet the fact remains that the commercial fibre is only produced in China and by rudest hand methods, Japan coming the nearest to establishing a commercial industry for the production of export fibre. Ramie is neither grown nor to any extent manufactured in the United States, though its culture was experimented with for years, and inventors and textile manufacturers have struggled with the machine problem, and with the after preparation and the spinning of the fibre. As far as this country is concerned, the fact that the Chinese fibre can be laid down in San Francisco for about 4 cents a pound condenses the entire ramie situation into a nutshell. Cultivation in this country would not pay at such prices, and there is not a machine in existence that could produce enough marketable fibre in a day to pay for the cost of running the machines when American wages are considered.

Ramie manufactures have been on the market for years, derived from European sources, and made from raw fibre produced in China. And many manufactures made in whole, or part, from ramie are sold as something else, because the fibre is unknown to the public, or because it is used as an adulterant, as in silk fabrics. See CHINA, CORDAGE, CORDAGE INDUSTRIES, FIBRE HEMP, ROPE.

RAMILLIES — RAMPOLLA

Consult 'Report on Rhea Fibers' (Watson, 1875); Bulletin Royal Kew Gardens; Dictionary Economic Products of India; Reports (1, 2, and 7) Office of Fibre Investigations, Department of Agriculture; also the French publications of Favier, De Landtsheer, Michatte, Roux, Ringlemann, and the ramie literature published by the Ministry of Agriculture of France.

CHAS. RICHARDS DODGE.

Ramillies, rā-mē-yē, a village of Belgium, in the province of Brabant, 13 miles north of Namur and 28 miles southeast of Brussels. On 23 May 1706 the Duke of Marlborough gained here a signal victory over the French under Marshal Villeroy and the Elector of Bavaria. The numbers were about 60,000 on each side; the loss of the allies was about 4,000 men, that of the French 15,000. The consequence of this battle was the immediate evacuation by the French of the chief strongholds in the Netherlands. See SPANISH SUCCESSION, WAR OF THE.

Ramirez, rā-mē'rēth, **Ignacio**, Mexican poet and philosopher: b. San Miguel el Grande 23 June 1818; d. Mexico 15 June 1879. He was descended from a family of pure Aztec blood, received a good education and early devoted his attention to literature. He founded 'Don Simplicio' in 1846 and was author under the pseudonym 'The Necromancer' of many philosophical articles and satirical poems. His writings have never been collected, but his 'Manual of Rudimentary Knowledge' was published in 1884.

Ramman, rām'man, or **Rimmon**, a deity worshipped by the Babylonians and sometimes called also Hadad. He was the god of the all-pervading atmosphere, especially of the winds. In this respect he may be likened to the Meeruts, or storm gods of northern India, for his name is derived from a Babylonian word meaning "loud sounding" or "bellowing." In the Bible "the House of Rimmon" is spoken of as his temple at Damascus (2 Kings v. 18). He is symbolized by the bull; is the god of storms and floods and of the charge of battle and is represented armed with thunderbolt and battle-axe. Consult: Baethgen, 'Beiträge zur semitischen Religionsgeschichte' (1902); Jastrow, 'Religion of Babylonia and Assyria' (1898).

Rammohun Roy, rām-mō-hūn' roi, Hindu religious reformer: b. Burdwan district, province of Bengal, India, 1772; d. Stapleton Park, near Bristol, England, 27 Sept. 1833. He was a Brahman of strict education, but early renounced the polytheism of Brahminic theology. For five years he was dewan, or principal native officer in the collection of the revenues, in one of the districts of East India company's services. He afterward studied Latin, Greek, and Hebrew. A careful study of the sacred writings of the Hindus had convinced him that the prevailing religious notions of the Hindus were grounded upon a gross perversion of their religion, the original records of which appeared to him to inculcate a system of pure theism. He now became anxious to reform the creed and practice of his countrymen, and determined to devote his talents and his fortune to this undertaking. A work of his in Persian on 'The Idolatry of all Religions' aroused much protest. In 1814 he went to live in Calcutta, where as early as 1818 he had united a number of intelligent Hindus

in a species of monotheistic worship. He translated the Vedānta, a compendium of the doctrines contained in the Vedas or ancient sacred books of the Hindus, from the Sanskrit into the Bengali and Hindustani languages, and distributed the translation gratuitously. This he afterward published in English, for the purpose of proving to his European friends "that the superstitious practices which deform the Hindu religion have nothing to do with the pure spirit of its dictates." From the perusal of the New Testament he found (he says) the doctrines of Christ more conducive to moral principles, and better adapted for the use of rational beings, than any other which had come to his knowledge. In 1820 he accordingly published the 'Precepts of Jesus the Guide to Peace and Happiness,' consisting chiefly of a selection of moral precepts from the Evangelists, and Unitarian in its character. On 23 Jan. 1830 he founded at Calcutta the Brahmiya Somaj, from which was derived the Brahmo Somaj (q.v.).

Rammohun Roy, in his doctrinal views, was a Unitarian, holding, however, the pre-existence and superangelic dignity of Christ, and considering the doctrine of the Trinity as a species of polytheism. He believed possible a combination of Brahminism and Christianity. His views were at first much misunderstood in England, and it appears that even Bishop Heber regarded him as an atheist. In 1830 he went to England in the character of ambassador from the king of Delhi (who gave him the title of Rajah). Consult: Carpenter, 'A Review of the Labors, Opinions, and Character of Rajah Rammohun Roy' (1833); Fox, 'Discourse on Occasion of the death of Rajah Rammohun Roy' (1833); Max Müller, 'Biographical Essays' (1883).

Ramo'na, a novel by Mrs. Helen Hunt Jackson, published in 1884. It is a picturesque, sympathetic, and faithful picture of Spanish and Indian life in California. Though the story is a passionate appeal for justice to the Indian it is in form one of the most delicate and beautiful examples of romantic literary art that English affords.

Ram'pion, a biennial herb (*Campanula rapunculus*) of the order *Campanulaceae*. It grows about 30 inches tall, has a parsnip-like root, obovate leaves, lilac flowers in a spike or raceme, and very small seeds. It is a native of Asia, Europe and northern Africa, where it is cultivated for its roots and leaves, the former of which are used like radishes, the latter like spinach. The plants do best in light, rich loam, partially shaded and well supplied with moisture but not wet. Since early spring sown plants are likely to run to seed, other sowings should be made in early summer. The plant is less popular in America than abroad.

Rampolla, rām-pōl'lā, **Mariano**, MARQUIS DEL TINDARO, Roman prelate: b. at Polizzi, Sicily, 17 Aug. 1843. Born of an aristocratic family he was educated at Rome and took priest's orders at 23. Several years later he entered diplomacy and was made secretary to the Papal nunciature at Madrid. During the absence of the Nuncio Simonei in 1876 he acted so brilliant a part during the Carlist war as to secure his appointment as secretary of the Congregation of the Propaganda. In 1885, being then Papal Nuncio

at Madrid, he proposed Pope Leo XIII. as arbitrator in the dispute between Spain and Germany regarding the Caroline Islands. In 1887 he was created cardinal and made papal secretary of state which post he held until the appointment of the new Pope Pius X. in 1903. The foreign policy of the Vatican was influenced by him and consisted of a conciliatory attitude toward France together with an opposition to the Triple Alliance, with the ultimate end in view of re-establishing the temporal power of the pope. Upon the death of Leo XIII. Cardinal Rampolla was one of the most prominent candidates to the succession.

Rāmpur, rām-poor', India, (1) capital of a state of the same name, on the left bank of the Kosila River, 18 miles east of Moradabad. It is the residence of the nawab, who represents the Rohilla chieftain of Rohilkhand. A lofty mosque is a specimen of oriental magnificence. The place is famous for its shawls, damask, sword-blades and jewelry. Pop. (1901) 77,862. (2) The state under the superintendence of the government of the United Provinces has an area of 899 square miles. Pop. (1901) 532,067.

Ramsay, rām'zī, Allan, Scottish poet: b. Leadhills, Lanarkshire, 15 Oct. 1686; d. Edinburgh 7 Jan. 1758. The death of his father in early life forced him to seek a means of livelihood in the Scottish capital. There he became bound as an apprentice to a wig-maker, which occupation he continued after his apprenticeship had ceased. The exact period when he commenced bookselling is unknown, but he is said to have been the first who established a circulating library in Scotland. The library continued to exist till a comparatively recent period. His first shop, as we learn from the imprint of some of his books, was "at the sign of the Mercury, opposite to Niddry's Wynd"; but in 1726 he removed to a house at the east end of the Luckenbooths, and adopted for his sign the heads of Ben Jonson and Drummond of Hawthornden. In 1721 he published a collection of his poems which was so liberally subscribed for that he is said to have cleared by it 400 guineas. These poems had originally appeared on separate broadsheets and sold for a penny each. In 1724 the first volume of 'The Tea-Table Miscellany,' a collection of songs appeared, which was soon followed by two others. Shortly afterward he brought out 'The Evergreen, being a Collection of Scots Poems wrote by the Ingenious before 1600,' which was equally successful. In 1725 appeared his famous pastoral, 'The Gentle Shepherd.' Its success was instantaneous, and edition followed edition with great rapidity. In 1728 a second quarto volume of his poems appeared; and his 'Thirty Fables,' undoubtedly the best of Ramsay's lesser productions. He was now at the height of his celebrity, and his shop was the common resort of the literary characters and wits of Edinburgh. He spent the last 12 years of his life in a quaint house he had built on the north side of Castle Hill, although he did not give up his shop until within three years of his death. He was buried in Greyfriars' Churchyard, where a monument has been erected. Another monument, erected in 1865, stands in Princes' Street Gardens. Consult 'Life' by Smeaton (1800); Graham, 'Scottish Men of Letters in the 18th Century' (1901).

Ramsay, Allan, Scottish portrait painter, son of the preceding: b. Edinburgh 1713; d. Dover 10 Aug. 1784. He studied art in London and in Italy, and by 1758 had achieved a high reputation. George III. appointed him principal court painter. Walpole regarded some of his portraits of women superior to Reynolds'. He painted portraits of Gibbon, Chesterfield, Hume, Rousseau, and many others, now in the National Portrait Gallery and the gallery at Edinburgh.

Ramsay, Sir Andrew Crombie, Scottish geologist: b. Glasgow, Scotland, 31 Jan. 1841; d. Anglesey, England, 9 Dec. 1891. In 1841 he joined the geological survey, with which he was connected until 1881. He became professor of geology at University College, London, in 1848; was lecturer at the School of Mines 1851; president of the Geological Society 1862; and director-general of the Geological Survey and the Museum of Practical Geology 1872-81. He was popular as a lecturer, and held the theory that many lake basins are the result of glacial excavations. As a geologist he devoted himself to stratigraphy to the exclusion of paleontology and petrography. His works include: 'Old Glaciers of North Wales and Switzerland' (1860); 'The Physical Geology and Geography of Great Britain' (1872); etc.

Ramsay, Andrew Michael (CHEVALIER RAMSAY), Scottish scholar: b. Ayr, Scotland, 9 June 1686; d. Saint Germain-en-Laye, France, 6 May 1743. He was educated at the universities of Edinburgh and Saint Andrews and being deeply interested in theological matters he went to Leyden where he formed a friendship with the mystic Poirret through whom he visited Fenelon, archbishop of Cambrai, in France in 1710. The latter took a deep interest in Ramsay, succeeded in converting him to the Roman Catholic faith, and kept him with him until his death in 1715 when he bequeathed to Ramsay his papers. Ramsay then became tutor to the Duc de Châteaune-Thierry and subsequently acted in the same capacity to the sons of the Pretender, Francis Edward, at Rome. He visited England in 1730, was elected to the Royal Society and on his return to Paris became tutor to the Vicomte de Turenne. His writings were published in excellent French, but though of considerable merit and very popular in his day, are now rarely read. They include: 'Essai Philosophique sur le Gouvernement Civil' (1721); 'Vie de Fénelon' (1723); 'Poems' (1728); 'L'Histoire du Vicomte de Turenne' (1735); etc.

Ramsay, David, American physician and historian: b. Lancaster County, Pa., 2 April 1749; d. Charleston, S. C., 8 May 1815. He studied medicine and practised in Charleston, where he soon acquired celebrity. He was a field-surgeon in the Continental army, was elected to the State legislature in 1776, was a prisoner of the British in 1780-1, and in 1772-6 served in the Continental Congress, acting as president in 1775-6. He was a member of the South Carolina legislature in 1801-15 and was president of the State senate when he was killed by a lunatic. He labored zealously with his pen to promote the cause of the American independence, and among his publications are: 'The History of the American Revolution' (1785); 'The Life of Washington' (1789); 'The History of South Carolina' (1809); 'Universal

History Americanized, or an Historical View of the World, from the Earliest Record to the 19th Century' (12 vols. 1816-17); etc.

Ramsay, Edward Bannerman, Scottish Episcopal clergyman: b. Aberdeen 31 Jan. 1793; d. Edinburgh 27 Dec. 1872. He was the son of Alexander Burnett, but adopted the name of his grand-uncle, Sir Alexander Ramsay, by whom he was brought up. Educated at Cambridge, he took holy orders and went to Edinburgh in 1823 as a clergyman of the Scottish Episcopal Church, becoming dean of the diocese in 1846. He is best known by his 'Reminiscences of Scottish Life and Character' (1858), which has had great popularity. Among other works by him are: 'Lectures on Handel' (1862); 'Pulpit Table-Folk' (1868).

Ramsay, Francis Munroe, American naval officer: b. Washington, D. C., 5 April 1835. He was appointed midshipman in 1850, was graduated from the United States Naval Academy in 1856, and in the Civil War participated in the engagements at Haines' Bluff, Yazoo River, Milliken's Bend, and later commanded the gunboat Unadilla of the North Atlantic Squadron. He was superintendent of the United States Naval Academy in 1881-6, was promoted rear-admiral in 1894, served as chief of the Bureau of Navigation in 1889-97; and in the latter year was retired on reaching the age limit.

Ramsay, Nathaniel, American soldier: b. Lancaster County, Pa., 1751; d. 25 Oct. 1817. He was graduated from Princeton in 1767, studied law, was admitted to the bar in 1771, and in 1776 entered the Continental army with rank as lieutenant-colonel. He greatly distinguished himself at the battle of Monmouth in 1778, when he with Colonel Stewart checked the advance of the British while Washington rallied the main army. He was severely wounded, taken prisoner, and held until 1780 when he was shortly afterward retired. With the exception of 1786-7, when he was a member of Congress from Maryland, he saw no further public service.

Ramsay, Sir William, Scotch chemist, nephew of Sir A. C. Ramsay, the geologist: b. Glasgow 2 Oct. 1852. He was educated at Glasgow and Tübingen, was assistant in the "Young" chemical laboratory 1872-4, and at Glasgow University 1874-80, and, after seven years as professor of chemistry at University College, Bristol (six as its principal), in 1887 he became professor of chemistry at University College, London. A member of most of the royal academies, philosophical, physical and chemical societies of the world, he won his chief repute for his study of rare gases and their discovery; with Lord Rayleigh in 1894 he discovered argon (q.v.), and alone isolated helium, krypton, neon and xenon (qq.v.). In the investigation of the nature and properties of radium he took a prominent part, and in November 1903 claimed that he had proof that helium is the gaseous emanation of radium (q.v.)—a discovery which would overset the law of the stability of the elements. He was made K.C.B. in 1902. He wrote 'The Gases of the Atmosphere, the History of their Discovery' (1896).

Ramsay, William Mitchell, Scottish archaeologist and historian: b. Glasgow 15 March

1851. He was educated at the universities of Aberdeen, Oxford, and Göttingen, was Oxford traveling student in 1880, and from that date onwards has traveled extensively in Asiatic Turkey. In 1885 he was appointed to the chair of classical archaeology at Oxford, and since 1886 has been professor of humanity (Latin) in the University of Aberdeen. He has made a special study of the geography and topography of Asia Minor, and among his works are: 'The Historical Geography of Asia Minor' (1890); 'The Church in the Roman Empire before A.D. 170' (1893), dealing with St. Paul in Asia Minor and the early persecutions of the Christians; 'The Cities and Bishoprics of Phrygia' (1895-7); 'St. Paul the Traveler and the Roman Citizen' (1895); 'Impressions of Turkey' (1897); 'Was Christ Born at Bethlehem?' (1898); 'Historical Commentary on the Epistle to the Galatians' (1899); 'The Education of Christ' (1902).

Ramsden, rāmz'den, Jesse, English mechanist and optician: b. Halifax, Yorkshire, 6 Oct. 1735; d. Brighton, Sussex, 5 Nov. 1800. He was apprenticed to a cloth-worker, but subsequently applied himself to engraving, and in the course of his employment having to engrave several mathematical instruments, finally constructed them himself. He opened a shop in the Haymarket, whence he removed to Piccadilly, where he remained until his death. Ramsden obtained a premium from the board of longitude for the invention of a machine for the division of mathematical instruments. He also improved the construction of the theodolite, the pyrometer for measuring the dilatation of bodies by heat, the barometer for measuring the height of mountains, the refracting micrometer and transit instrument and quadrant. He made great improvements in Hadley's quadrant and sextant, reducing the limits of error from 5' to 30"; and procured a patent for an amended equatorial. He was chosen a fellow of the Royal Society in 1786, and such was his reputation that his instruments were bespoke from every part of Europe. He received the Copley medal from the Royal Society in 1795 in recognition of the importance of his various inventions.

Ramseur, rām's'èr, Stephen Dodson, American soldier: b. Lincolnton, N. C., 31 May 1837; d. Cedar Creek, Va., 19 Oct. 1864. He was graduated from West Point in 1860 and was assigned to garrison duty at Fortress Monroe. At the outbreak of the Civil War he resigned from the United States army to enter the Confederate service with rank as major of artillery. He served in the peninsular campaign, was later attached to "Stonewall" Jackson's command, performed gallant service at Chancellorsville and at Gettysburg in his capacity of brigadier-general, and was conspicuous for bravery in the battle of the Wilderness. In 1864 he received temporary rank as major-general, was engaged in the Shenandoah campaign, and was fatally wounded at the battle of Cedar Creek, where he was captured while covering the retreat of the Confederate forces.

Ramsey, rām'zī, Alexander, American politician and cabinet officer: b. near Harrisburg, Pa., 8 Sept. 1815; d. Saint Paul, Minn., 22 April 1903. He took a partial course at Lafayette College (Easton, Pa.), studied law at Carlisle,

Pa., was admitted to practice in 1839, in 1841 was elected chief clerk of the Pennsylvania house of representatives, and in 1843-7 was a Whig representative in Congress. In 1848 he was chairman of the Whig State committee, and on 2 April 1849 was appointed governor of Minnesota, established as a territory 3 March 1849. He concluded treaties with the Ojibways and Sioux in 1851, and a second treaty with the Ojibways in 1863. In 1855 he became mayor of Saint Paul, in 1859 was elected governor of the State of Minnesota, being the Republican candidate for the first State campaign, and by re-election held the post until his resignation 10 July 1863. He then served in the United States Senate two terms, ending in 1875. While in the senate he visited France in the effort to secure a cheaper rate of international postage. In 1879-81 he was secretary of war in Hayes' cabinet. He was a leading spirit of the Minnesota Historical Society, of which he was the first president (1849-63). He was the first Civil War governor to offer volunteers to Lincoln.

Ramsgate, rāmz'gāt, England, on the Isle of Thanet, in the County of Kent, four miles from Margate, is a seaport and popular seaside resort. It is situated in the valley between chalky cliffs and has a fine stretch of sandy beach. The chief places of interest are the theatre, music-hall, assembly-room, iron promenade pier, and churches. There is an excellent harbor, extensive bathing establishments; of historical interest are: an ancient Anglo-Saxon graveyard on Ossengal Hill, about one mile from the town; Pegwell Bay, the landing place of Hengist and Horsa, and Cliffs' End, where a cross marks that of Saint Augustine. There is some ship-building, rope-making and a considerable fishery. Pop. (1901) 27,693.

Ramus, rā'mūs, **Petrus**. See RAMÉE, PIERRE.

Ra'na. See FROG.

Ranavalona III., former queen of Madagascar: b. about 1861. She succeeded her aunt, Ranavalona II., in 1883 and in that year married the prime minister Rainilaiarivony who had been prince consort to her aunt. She was only nominally queen as the government had been controlled by the prime minister since 1864. The French succeeded in establishing a protectorate over the island in 1895, Ranavalona retained a nominal sovereignty until 1897 when the island was declared a French colony and the queen was deposed and exiled to Algeria.

Ranc, rānk, **Arthur**, French politician and author: b. Poitiers, 20 Dec. 1831. He was educated at the college in Poitiers; studied law in Paris in 1853; became involved in the disorders of the democratic party, was arrested and deported to Africa. Returning to Paris after the amnesty of 1859, he contributed to the 'Courier du Dimanche,' the 'Nain Jaune,' the 'Journal de Paris' and other journals. For certain articles written for the 'Nain Jaune' he was imprisoned for four months. Under Gambetta he became director of police and in 1871 was elected to the National Assembly, but, owing to his disagreement with the arrangements for peace he resigned and was elected a member of the Commune. He resigned from that body on account of its violence. In 1873 he again became a member of the National Assembly. Later he was impeached for the part he had played

during the Commune, and in 1875 during his absence in Belgium was condemned to death in *contumaciam*. The amnesty of 1879 allowed his return to France, and in 1881 he became deputy from the Seine and in 1891 a senator. He wrote a political romance, 'Sous l'Empire' (1872), also 'De Bordeaux à Versailles' (1877); 'Le Roman d'une Conspiration' (1868).

Rancagua, rān-kāg'wā, Chile, the capital of the province of O'Higgins, 45 miles by rail south of Santiago. It is an agricultural centre with an active domestic trade. The Spaniards here won an important victory over the revolutionary forces in 1814. Pop. (1895) 6,665.

Rancé, rān-sā, **Dominique Armand Jean le Bouthillier de**, founder of the reformed order of La Trappe: b. Paris 9 Jan. 1626; d. 26 Oct. 1700. At 11 he was appointed canon of Notre Dame, and at 13 wrote a commentary on the Odes of Anacreon. After being graduated at the Sorbonne, he was ordained priest (1651) and before long was preferred to no fewer than six benefices. Residing at Paris, in receipt of a large income in addition to his private fortune, he gave himself up to a life of dissipation. In 1657, however, a change took place in his manner of life, and he determined to enter the cloister. He disposed of his estate of Veret, near Tours, applying the proceeds to religious purposes, and demitted all his benefices except the priory of Boulogne and the abbey of La Trappe. Retiring to the latter place in 1664, he began the strictest reforms. (See LA TRAPPE.) In consequence of his growing infirmities he resigned his charge of the abbey in 1695. Consult Marsoillier, 'Vie de Rancé' (1703); Gaillardin, 'Trappistes' (1844); Pfannenschmidt, 'Geschichte der Trappisten' (1873).

Ranching, a term derived from the Spanish-American word "rancho," originally meaning a place where herdsmen eat and sleep, but gradually extended to mean a grazing farm. Some of these ranches are of vast extent, especially in Old Mexico and in South America, and include hundreds of square miles. In Texas, Colorado and other western States and Territories, also, there are very large ranches, from which come the supplies of cattle for the American and foreign markets. With the growth of population there has been a marked reduction in great individual holdings of land, but some of the cattle-farms are still very extensive. The cattle are herded by a mixed class of men known as cowboys, which includes students from college, rough and honest frontiersmen, and others with a record that has driven them from places where they are better known. It was chiefly from the cowboy element that President Roosevelt recruited his Rough Riders for the Spanish-American war.

The cowboys round up the cattle once or twice a year, when the steers three years old are separated from the main herd and sent to market, and the calves are branded. The cattle of the ranches have been much improved within recent years by crossing with domestic breeds.

Rand, rānd, or **Witwatersrand**, South Africa. See WITWATERSRAND; TRANSVAAL COLONY.

Randall, rān'dal, **Alexander Williams**, American legislator: b. Ames, N. Y., 31 Oct.

1819; d. Elmira, N. Y., 25 July 1872. He studied law, was admitted to the bar and in 1840 established a law practice at Waukesha, Wis. He was appointed postmaster there and in 1847 was a member of the convention which framed the State constitution. In 1855 he was elected to the State legislature, was judge of the 2d district in 1856, and in 1857-61 was governor of Wisconsin, rendering important aid in raising troops for the Union army. In 1861-2 he served as minister to Italy, was assistant postmaster-general in 1862-6, and postmaster-general in 1866-9. He then retired from public life and engaged in law practice at Elmira until his death.

Randall, Emilius Oviatt, American author: b. Richfield, Ohio, 28 Oct. 1850. He was graduated from Cornell University in 1874, studied law in the Ohio State University; was admitted to the bar in 1890 and became professor of law at the Ohio State University in 1893. He was appointed secretary of the Ohio State Archaeological and Historical Society in 1894, and official reporter of the Ohio supreme court in 1895. He was editor of 'Bench and Bar of Ohio'; 'Ohio State Reports of the Supreme Court Decisions' (17 vols.); and since 1897 has also edited the 'Ohio Archaeological and Historical Quarterly.' He has written: 'History of the Separatist Party of Zoar' (1899); 'History of Blennerhasset' (1899).

Randall, George Morton, American military officer: b. Ohio 8 Oct. 1841. At the outbreak of the Civil War he entered the Union army, where he received a commission as 2d lieutenant. He received steady promotion, was distinguished for gallantry at Antietam and Petersburg, and was mustered out of the volunteer service in 1865 with the rank of lieutenant-colonel. He was commissioned captain in the regular army in that year, promoted colonel in 1890 for gallant services in the Indian warfare in Arizona in 1873-4; commissioned brigadier-general of volunteers at the outbreak of the Spanish war in 1898, and on the reorganization of the regular army in 1901 received rank as brigadier-general.

Randall, James Ryder, American journalist and poet: b. Baltimore, Md., 1 Jan. 1839. He was educated at Georgetown College, D. C., taught for a while in a Louisiana college, and then turned to journalism. In 1861 he wrote 'Maryland, My Maryland,' a song which when set to music became, next to 'Dixie,' the most popular of the Confederate war-songs and is considered by many to be the best American martial lyric. None of his other songs achieved the fame of this, but several of them are of notable excellence. Among them are: 'Stonewall Jackson,' and 'There's Life in the Old Land Yet.' After 1866 he was for many years the editor of the 'Constitutionalist' of Augusta, Georgia.

Randall, Samuel Jackson, American statesman: b. Philadelphia 10 Oct. 1828; d. Washington, D. C., 12 April 1890. Educated in the schools of his native city, he began life as a silk merchant's clerk and later entered into partnership in a firm of wholesale iron merchants. But politics was more attractive to him than business. He served four years as member of the city council and in 1858 was elected to the

State senate. He enlisted with the City troop of Philadelphia at the beginning of the Civil War and served under Gen. Thomas' command in the 2d United States cavalry. He was promoted to orderly sergeant, then quartermaster, and finally captain of his company. During the battle of Gettysburg he was advanced to provost-marshal. In 1862 he was elected to Congress and was a member of that body for 28 years. The first eight years of his career in Congress were uneventful; but in the 43d Congress he served with Blaine, Garfield, Banks, and S. S. Cox on the committee on rules, and took the lead in the opposition to the Force Bill in order to defeat its passage as law and secure for himself the leadership of the Democratic party in Congress. He was elected Speaker of the House at the 2d session of the 44th Congress and re-elected by the 45th and 46th; hence it fell to him to preside during the dispute over the Presidential election of 1876. He was not in sympathy with the settlement of the difficulty by means of an electoral commission. Although always a Democrat, he took the opposite view to that of his party on the subject of protection at the period when tariff discussions were uppermost in Congress. He was an indefatigable worker and never shirked the arduous labor of committees, insisting always on economy and honesty in the management of public affairs. Hence he served as an immense safeguard of the national treasury.

Randegger, rän'dëg-gër, Alberto, Austro-English composer and conductor: b. Trieste 13 April 1832. He studied pianoforte under Lafont and composition under L. Ricci, and before he was 20 was known as composer of several masses and two ballets. His next work was an opera, 'Il Lazzarone,' to a libretto by Rossi. He became musical director in various Italian theatres, and brought out his second opera, 'Bianca Capella,' at Brescia in 1854. In that year he removed to London, where he has since resided, becoming naturalized. He has been teacher and director of the Royal Academy of Music, conductor of Italian opera at Covent Garden, and of concerts at Queen's Hall and the Norwich Festival. A comic opera, 'The Rival Beauties,' was produced in 1864. He was made Knight of the Crown of Italy in 1892.

Randers, rän'dërs, Denmark, in Jutland, eight miles from Randers Fjord, an important port, whose chief exports are butter and eggs; chief imports sugar, petroleum, coal, and iron. Its celebrated gloves, its manufactures of hosiery, cutlery, railway carriages, calico-printing works, and distilleries are the chief industries. Pop. (1901) 20,057.

Randolph, rän'dölf, Alfred Magill, American Protestant Episcopal bishop: b. Winchester, Va., 31 Aug. 1836. He was graduated at William and Mary College in 1855 and at the Virginia Theological Seminary in 1858, and took priest's orders in 1860. He was rector of St. George's Church, Fredericksburg, Va., 1860-2, chaplain in the Confederate army 1863-5, and rector of Emmanuel Church, Baltimore, Md., 1867-83. In the latter year he was elected coadjutor-bishop of Virginia. In 1892 the diocese was divided and he then became bishop of southern Virginia. He has published 'Reason, Faith, and Authority in Christianity' (1902).

RANDOLPH

Randolph, Edmund Jennings, American statesman: b. Williamsburg, Va., 10 Aug. 1753; d. Clarke County, Va., 13 Sept. 1813. He was educated at William and Mary College and afterward admitted to the bar. He was Virginia's first attorney-general, was member of Congress 1779-82 and governor of Virginia 1786-8. He was a member of the convention that framed the Federal constitution, though he did not approve or sign the document when completed. However, he urged Virginia to accept it, feeling the necessity of union of the States. He was a leader in the work of codifying the Virginian laws begun in 1788. In 1789 Washington appointed him attorney-general, and in 1794 he succeeded Jefferson as secretary of state. During the pending of the Jay treaty, Fauchet, the French minister to the United States, sent home some despatches to his country which were intercepted by an English ship and through the English minister were transmitted to Washington. They were kept by the President for eight days before their contents were disclosed to Randolph. Feeling that others had been consulted regarding the matter before he was apprised and that he must consequently be prejudged, he resigned his office after denying the allegations of the despatches. He retired to Virginia and resumed the practice of the law, but his public career was blighted and his memory bore the stain of the accusations against him until his vindication was presented by Moncure D. Conway in an article, 'A Suppressed Statesman,' in 'Lippincott's Magazine' for September 1887, followed by a biography, 'Omitted Chapters of History Disclosed in the Life and Papers of Edmund Randolph' (1888).

Randolph, John, of Roanoke, American statesman: b. Cawsons, Chesterfield County, Va., 2 June 1773; d. Philadelphia 24 June 1833. He was of an old and wealthy Virginia family. His father died young, and his mother married St. George Tucker, who directed his early education. Later he attended the grammar school of William and Mary College; in 1787 went to Princeton for a few months, and the following session to Columbia College, which ended his academic training. In spite of his protestations of ignorance he was well educated, wrote and reasoned well. He read law and began to practise, but entered into politics, and in 1799 was elected to Congress on a platform denouncing the Alien and Sedition laws. Randolph was in the House of Representatives 1799-1813, 1815-17, and 1819-25. He was a member of the Senate 1825-29, and in 1829 was a member of the Virginia Constitutional Convention. In Congress he soon became the leader of the Democratic-Republican opposition, and after the defeat of the Federalists, was the leader of the administration party, but soon fell out with Jefferson, and became an independent with a few followers called "Quids." Throughout his public career Randolph was a consistent, strict constructionist. In his first speech he advocated a reduction of the "mercenary" army; he led in the impeachment (1804-5) of Justice Chase, of the Federal District Court; he denounced the settlement of the Yazoo frauds; and was the enemy of fraud and corruption in every form. Brought up in the midst of war, he hated it, opposing all measures leading to the War of 1812, and his opposi-

tion to the administration cost him his seat in 1813. Returned to Congress in 1815, he strongly opposed the national reaction that followed the War of 1812. He disliked slavery, but denounced the Missouri Compromise as a surrender of principles by both sides. He invented the term "dough faces," as applied to Northern men who made compromises with slavery for reasons of expediency. He supported Jackson for the Presidency, and denounced the Adams-Clay understanding as "a combination of Puritan and blackleg." A duel with Clay followed (1825), in which Randolph threw away his fire and offered Clay his hand. In 1830 Jackson appointed him minister to Russia. Resigning because of ill health, Randolph returned to America (1831) and opposed Jackson in the Nullification controversy. Re-elected to Congress in 1832, he died before taking his seat. Randolph was a strange compound of contradictory elements. At times he was a deist; oftener an emotional Christian. He was a far-sighted statesman, an eloquent speaker, a master of satire and vindictive; at times he spoke nonsense. Eccentric and irritable in public, he was fond of children and was loved by them. By his will he emancipated his 318 slaves, providing for their support. With clearer vision than most of his contemporaries, he foresaw the grave danger to the South from the slavery question in politics and pointed out the course which that section must follow. He was never married, his fiancée, the beautiful Maria Ward, having broken her engagement with him to marry his cousin, Peyton Randolph. An aristocrat, he believed in the democratic theories of the French Revolution, but admired Edmund Burke. In his later years, his mind was affected by disease and the use of drugs to deaden pain, and by domestic troubles. In personal appearance Randolph was tall, very slender, with a dark, keen face, and long thin fingers, which he pointed or shook at his opponents when speaking. "Little Jack" was a beautiful boy; John Randolph was an ugly man. Consult: Garland, 'The Life of John Randolph of Roanoke' (1881); Henry Adams, 'John Randolph' (1882); Trent, 'Southern Statesmen of the Old Régime' (1898).

WALTER L. FLEMING,

Professor of History, West Virginia University.

Randolph, Peyton, American patriot, president of the 1st Continental Congress: b. Williamsburg 1723; d. Philadelphia 22 Oct. 1775. He was graduated at William and Mary College, and, sent to complete his education in England, studied law at the Temple. In 1748 he became king's attorney for the colony, and the same year was chosen a member of the House of Burgesses. He was chairman of a committee authorized to revise the laws of the colony, and was among the most active and influential members of the assembly. In 1764 the Virginia House of Burgesses voted an address to the king against the passage of the Stamp Act, which Randolph drew up. On 12 April 1766 he was made speaker of the House of Burgesses, and resigned his office of attorney-general. In the measures of opposition to the English he now took a conspicuous part. In March 1773, on the reception of copies of an address and resolution from the Massachusetts assembly, Randolph was prominent in urging instant and bold action. In the convention which

John Hurdolph

RANDOLPH — RANDOLPH-MACON SYSTEM

met in August 1774, at Williamsburg, he presided, and was one of the delegates elected to the Continental Congress appointed to meet in Philadelphia in the following September. On the assembling of that body he was unanimously elected its president. In 1775 he presided over the second convention of Virginia and was speaker of the House of Burgesses.

Randolph, Thomas, English poet and dramatist: b. Houghton, Northamptonshire, 15 June 1605; d. Blatherwyke, Northamptonshire, 17 March 1635. He was educated at Cambridge, and was admitted to a fellowship, began early to write, and gained the friendship of Shirley and Ben Jonson, who adopted him among his poetic "sons." He seems to have lived a boisterous life, which was doubtless the cause of his early death. He left a number of bright, fanciful poems, and was author of several dramas successfully performed by the university students. 'Aristippus, or the Jovial Philosopher' and 'The Conceited Peddler' were published in 1630, the first a satire on university education, the latter a monologue in the style of Shakespeare's 'Autolycus.' He also wrote: 'The Muses' Looking Glass' and 'Amyntas,' published posthumously with his poems (1638); and 'Cornelianum Dolium' (1638) and 'Hey for Honesty' (1651) are credited to him. His collected works were edited by Hazlitt (1875).

Randolph, Thomas Jefferson, American legislator: b. Monticello, Albemarle County, Va., 12 Sept. 1792; d. Edge Hill, Albemarle County, Va., 8 Oct. 1875. He was for several years a member of the State legislature of Virginia, where he introduced in 1832 a bill for the gradual abolition of slavery, and in 1842 another for the reform of the taxes, which was passed, and proved of assistance in placing the State on a sound financial basis. In 1851-2 he was a member of the convention for the revision of the Virginia Constitution, in Civil War time was a firm supporter of the Confederacy, and in 1872 presided over the National Democratic convention which nominated Horace Greeley for the presidency. As literary executor he edited the 'Life and Correspondence of Thomas Jefferson' (1829); and he wrote also 'Sixty Years' Reminiscences of the Currency of the United States.'

Randolph, Vt., town in Orange County; on the Central Vermont railroad; about 22 miles south by west of Montpelier. The town includes several villages. It is in an agricultural and lumbering region and its industries are connected largely with farming and lumbering. It has wooden ware factories, flour and lumber mills, and creameries. Its most noted institution is the Randolph State Normal School. It has a free public library. Pop. (1890) 3,232; (1900) 3,141.

Randolph Plan, in American political history, the name given the scheme of a Federal Constitution proposed in the Convention of 1787 by Edmund Randolph of Virginia. It contained 15 resolutions and proposed a correction of the Articles of Confederation; representation by population in two branches of Congress, the first chosen by the people, the second by State Legislatures; congressional control of taxation and commerce; congressional veto of State enactments; that Congress should choose the

executive; that the executive with part of the judiciary should have a limited veto on acts of Congress, and other less important provisions. The plan was favorably reported and many of its suggestions were used in the drafting of the Constitution.

Randolph-Macon (mă'kón) System of Colleges and Academies, a group of five institutions in Virginia, comprising: (1) Randolph-Macon College at Ashland, a college for men; (2) Randolph-Macon Academy at Bedford City; and (3) Randolph-Macon Academy at Front Royal, preparatory schools for boys; (4) Randolph-Macon Woman's College at Lynchburg; (5) Randolph-Macon Institute at Danville, a preparatory school for girls. These institutions are under the control of one board of trustees, which is self-perpetuating. The original institution is the college for men at Ashland, which was established under the auspices of the Methodist Episcopal Church, South, and received its charter from the Virginia legislature in 1830, thus being the oldest Methodist college in America. It was located near Boydton, Mecklenburg County, Va., and opened to students in 1832. The college obtained no permanent endowment until shortly before the Civil War, and was closed during the war. Much of the endowment was also rendered worthless, and the college reopened in 1866 under serious embarrassment. In 1868 its site was changed to Ashland, Va., and since that time its work has been successful and influential. The first of the affiliated schools was the Academy at Bedford City, founded in 1890; the Academy at Front Royal was established in 1892, and the Woman's College in 1893; the Institute at Danville was affiliated with the system in 1897.

The Randolph-Macon College at Ashland offers courses leading to the degrees of A.B. and A.M., graduation with distinction in four subjects additional to those required for the degree of A.B., is required for the degree of A.M. The A.M. courses are elective, and the elective system prevails to a limited degree in the A.B. course. Six students' aid funds are provided, four of which are for ministerial students, and several scholarships, the largest of which has a fund of \$10,000. Two literary societies are maintained by the students for literary and oratorical exercises. The buildings include Pace Lecture-Room Building, the Chemical Laboratory, Duncan Memorial Chapel, the Library, the Gymnasium, the Pettyjohn Hall of Science, and eight dormitories (1904). The library contained in 1904, 11,000 volumes. The grounds and buildings are valued at \$95,000; the productive funds amounted to \$250,000 in 1903-4, and the annual income to \$19,719. The students numbered 126, and the faculty 10.

The Randolph-Macon Woman's College offers courses leading to the degrees of A.B. and A.M. One year of graduate work in courses elected by the student is required for the master's degree. For the A.B. course the work of the first two years is prescribed, the last two years is largely elective; the electives are arranged in eight groups, one course in each group being the free choice of the student. Courses in music are offered; one course in the history of music is open to all college students and counts toward the A.B. degree; and a com-

RANGE — RANK

pletion of the course in either piano, organ or vocal music counts three hours toward the degree. The college occupies two buildings (1904), the main building and the Jones Memorial Library; the library contained 4,000 volumes in 1904. In 1903-4 the productive funds amounted to \$102,000, the annual income was \$65,500. The students numbered 268 and the faculty 28.

Range, (1) in gunnery, the horizontal distance to which a projectile is thrown. Strictly, it is the distance from the muzzle of the gun to the second intersection of the trajectory with the line of sight. A cannon lying horizontally is called the right level or point-blank range; when the muzzle is elevated to 45° it is called the utmost level. (2) In music, the whole ascending or descending series of sounds capable of being produced by a voice or instrument; the compass or register of a voice or instrument. (3) In natural science, the geographical limits within which an animal or plant is now distributed, and the limits in point of time within which it has existed on the globe. The first is called range in space, and the second range in time. In the case of marine animals, as the Mollusca, there is also a range of depth, as measured by the number of fathoms which constitute their superior and inferior limits. (4) As a nautical term: the length of cable a little in excess of the depth of water, ranged on deck ready to run out when the anchor is let go. Also a large cleat in the waist for belaying the sheets and tacks of the courses.

Range Finder. See FORTIFICATION.

Rangeley (rānj'li) **Lakes**, in Maine, near the western boundary; one of the lakes, Umbagog, is on the boundary between Maine and New Hampshire. The principal lakes are Umbagog, Richardson, Molechunkemunk, Mooselucmaguntic, Rangeley, and Kennebagog. A number of small bodies of water are connected with the lakes mentioned, and all are joined by short streams. The Rangeley Lakes are the headwaters of Androscoggin River (q.v.). They are noted for the wild and picturesque scenery, and the abundance of fish and game. The region is a favorite summer resort. Two railroads enter this section, one terminating at the town of Rangeley on Rangeley Lake, and the other at Bemis on Mooselucmaguntic Lake.

Ranger, rān'jēr, **Henry Ward**, American painter: b. Western New York 1858. He never attended an academy of art, but traveled through France, England, and Holland for several years, and returning to the United States was elected Associate of the National Academy of Design. Among his pictures are 'The Top of the Hill' (in the Corcoran Gallery); 'East River Idyll' (in the Carnegie Gallery); 'Pasture Lot'; 'Morning at High Bridge'; 'Bradley's Mill Pond.' Other of his pictures are marines, and as a landscape painter his works are fresh, vigorous and finely colored.

Rangoon, rān-goon', Burma, chief town and principal seaport of Lower Burma, on the left bank of the Hlaing or Rangoon River, in the Pegu Division, covers an area of 22 square miles, and is populated by Hindus, Mohammedans and Christians. The town occupies a long stretch of high land, incorporating villas whose spacious grounds lend to certain parts

almost a rural aspect. The wide streets are virtually boulevards bordered on either side by trees. The town is of recent growth, dating from about 1852. Among buildings may be mentioned the cathedrals, churches, government buildings, town-hall, law-courts, custom-house, hospital schools and colleges, and museum. The city enjoys most of the modern conveniences, including a good water supply. There is railway communication with Mandalay and Prome. A large foreign and inland commerce is also carried on by waterways. The main exports are rice and timber, besides raw cotton, precious stones, ivory, horns, and a variety of other articles. Cotton and woolen goods, machinery, coals, silk, salt and sugar are imported. The annual exports exceed £10,000,000. Rangoon was built in 1753 by Alosing-Choosa, the founder of the Burmese dynasty, and has since been the scene of many wars between Burmans and Peguans. The British restored it in 1825 to the Burmese, but annexed it in 1852. Pop. (1901) 232,326.

Ranjit Singh, rŭn-jēt' sing'h', founder of the Sikh kingdom in the Punjab, India: b. Gujranwala 2 Nov. 1780; d. 27 June 1839. His father was Maha-Singh, sirdar of Sukur-Chukeah. He lost both parents before he was 18, and though wholly without education set vigorously about consolidating and extending his power. At 20 he was appointed governor of Lahore by the Afghan Amir and calculated upon the fanaticism of the Sikhs for establishing his power over them. He secured European officers to organize his army, whose steadfastness and religious zeal Sir William Hunter has compared to the Ironsides of Cromwell. In 1809 he formed an alliance with the English through Charles Metcalfe, defining the Sutlej as the boundary between their respective territories, and to this engagement he always remained loyal. Having removed the danger of English combination with any of his native rivals, he actively pushed forward his conquests until his territory extended to and embraced Mŭltān on the south, Peshāwar on the west and Kashmir on the north. He obtained from Shāh Shujā, a refugee in Lahore, the Koh-i-nŭr diamond that had been carried off by Nādir Shāh from Delhi. Dissensions followed his death as none of his sons was capable of continuing his rule. Consult Griffin, 'Ranjit-Singh' (1892).

Rank, in the army and navy, a grade of various officers established by law. The highest rank in the American army is general; in the navy, admiral. Next to general is lieutenant-general, then major-general, and next brigadier-general. In time of peace the highest army officer is usually a major-general, the titles of general and lieutenant-general being bestowed only as marks of special distinction. The same conditions apply to the ranks of admiral and vice-admiral. There is at present one admiral, Dewey, and no vice-admiral, the nearest officers in rank being rear-admirals. A bitter controversy between the friends of the late Rear-Admiral Sampson and of Rear-Admiral Schley as to who was in command at the victory of Santiago prevented either from being made vice-admiral. The lowest military commissioned rank is second lieutenant; in the navy, ensign. *Brevet* rank is the title of a rank superior to that

actually held, without its pay or emoluments. At the close of the Civil War nearly all colonels, with good records, were brevetted brigadier-generals.

Ranke, răn'kê, Leopold von, German historian: b. Wiehe, Thuringia, 21 Dec. 1795; d. Berlin 23 May 1886. His preliminary education at Donndorf and Schulpforta was followed by studies in theology and philology in Leipsic. From 1818 to 1825 he taught classics in the gymnasium at Frankfurt, and then became professor of history at Berlin, largely because of the promise of his 'History of the Roman and Germanic Peoples from 1494 to 1535,' of which the first volume appeared in 1824. His coming to Berlin was the beginning of his study of Venetian history, which was chiefly due to his discovery of the valuable Relations of the Venetian ambassadors, a discovery which strengthened his belief in the importance of diplomatic and other documentary material. In 1827 he began the important study of civilization, first entitled 'Princes and Peoples of Southern Europe in the 16th and 17th Centuries,' and in its revised form called 'The Ottomans and the Spanish Monarchy in the 16th and 17th Centuries' (1877); and in the years immediately following wrote on the Servian Revolution (1829); 'The Conspiracy against Venice in 1618' (1831); and the lectures 'On the History of Italian Poetry' (1837). To the lectures delivered in 1833 may be dated the rise of the historical school known by his name, which, like the Heidelberg School, was Protestant in sympathy and impulses, but unpartisan in methods; its members include Waitz, best known for his studies of constitutional history, Giesebrecht, who wrote on the German Empire, von Sybel, author of the 'History of the French Revolution,' von Sybel's pupils, von Noorden and Maurenbrecher, and Dümmler, one of the editors of the 'Monumenta Germaniæ,' and Dove, Ranke's literary executor and one of the editors of volumes 7-9 of the 'History of the World.' From 1833 also dates the foundation of the 'Historisch-Politische Zeitschrift,' edited by Savigny, Ranke and others, and protesting against the extreme liberalism of the revolution of July; as well as the beginning of Ranke's great history of 'The Roman Popes in the Last Four Centuries' (1834-7; 10th ed. 1900), with its clear outline of the varied political and religious influences at work in Rome and its wonderful grasp of the meaning in a philosophic scheme of 'World-History' of the Papacy. It was followed and balanced by 'German History in the Time of the Reformation' (1839-47; 7th ed. 1894), and 'Twelve (originally Nine) Books of Prussian History' (1847-8; revised 1878-9), thus fulfilling in part his function as Prussian historiographer, a post to which he had been appointed in 1841. He was ennobled by the King of Prussia in 1865, and since 1858 had been president of the Munich Historical Commission. His academic activity ceased in 1871, but his work of research, authorship, and revision continued almost to the very day of his death. A monument was erected to him in Wiehe, in 1896.

He wrote 'French History, Especially in the 16th and 17th Centuries' (1852-61), 'English History in the 16th and 17th Centuries' (1859-67; revised and enlarged 1877-9), and

various studies in German history, among which the sympathetic 'History of Wallenstein' (1869; 5th ed. 1895) should be mentioned. But of the greatest importance as embodying Ranke's philosophical idea of universal history is the 'History of the World' (1880-8; 5th ed. 1896 sqq.), which is marked by thorough research, excellent critical judgment, and sharp, clear, and felicitous characterization, with a poetical vigor of style.

Ranke's complete works were edited by Dove; volumes 53 and 54 contain valuable auto-biographical matter. Consult also: Dove's biography in the 'Allgemeine deutsche Biographie'; sketches by Sybel, in 'Histor. Zeitschrift,' vol. 56; Prutz, in 'Unsere Zeit' (1886), and his son F. v. Ranke, in 'Deutsche Revue' (1903); Lorenz, 'Ranke, die Generationenlehre und der Geschichtsunterricht' (1891); Guglia, 'Leopold von Ranke' (1893); Ritter, 'Ranke: Seine Geistesentwicklung und seine Geschichtschreibung' (1896); Nalbandian, 'Ranke's Bildungsjahre und Geschichtsauffassung' (1901).

Rankin, Jeremiah Eames, American Congregationalist clergyman and educator: b. Thornton, N. H., 2 Jan. 1828; d. Cleveland, Ohio, 28 Nov. 1904. He was graduated from Middlebury College, Vt., in 1848 and entered the ministry, serving in various pastorates in Massachusetts, New York, and New Jersey. From 1889-1903 he was president of Howard University, Washington, D. C., resigning in the latter year. He was the author of numerous hymns, notably 'God be with You,' and also published 'Auld Scotch Mither and other Poems'; 'Christ His Own Interpreter'; etc.

Rankine, răn'kin, William John MacQuorn, Scottish scientist: b. Edinburgh 5 July 1820; d. Glasgow 24 Dec. 1872. He entered Edinburgh University, where he gained several prizes in the department of physics; in 1837 he took up civil engineering and in 1842 published his first book, 'An Experimental Inquiry into the advantage of Cylindrical Wheels on Railways.' In 1848 he began his researches in the domain of molecular physics, which occupied him at intervals throughout his life and form his chief claim to distinction in the domain of pure science. In 1855 he was appointed to the chair of engineering in Glasgow University, which position he held until his death. He published 'Manual of the Steam-Engine and other Prime Movers' (1859); 'Manual of Civil Engineering' (1861); 'Treatise on Shipbuilding, Theoretical and Practical' (1866); 'Machinery and Millwork' (1869). Consult memoir by Tait prefixed to his 'Miscellaneous Scientific Papers' (1881).

Ran'ney, William, American artist: b. Middletown, Conn., 9 May 1813; d. West Hoboken, N. J., 18 Nov. 1857. He learned drawing in Brooklyn, N. Y., and at the outbreak of the war with Mexico enlisted with the Texans. During the campaign he made sketches from the picturesque southwestern life, and after his return to Brooklyn, elaborated these into oil paintings of great interest, among which may be mentioned: 'Boone's First View of the Kentucky'; 'On the Wing'; 'Washington on His Mission to the Indians' (1847); 'Duck-Shooting' (Corcoran Gallery, Washington); 'The Sleigh Ride'; and 'The Trapper's Last Shot.'

Ransom, Matthew Whitaker, American soldier and legislator: b. Warren County, N. C., 8 Oct. 1826; d. 8 Oct. 1904. He was graduated from the University of North Carolina in 1847, was admitted to the bar the same year, and in 1852 was elected attorney-general but resigned in 1855. He entered political life and in 1858-60 served in the State assembly. He was untiring in his efforts to avert the Civil War, but when North Carolina seceded he entered the Confederate army and served with ability through the war, attaining the rank of major-general in 1865. Afterward he resumed his law practice, was elected United States senator in 1872 and served until 1895, when he was appointed minister to Mexico and served until 1897 when he returned to the United States and re-engaged in law practice at Weldon, N. C.

Ransom, Robert, American soldier: b. Warren County, N. C., about 1828. He was graduated from West Point in 1850, was brevetted 2d lieutenant of dragoons, and served in various parts of the West until appointed assistant instructor of cavalry tactics at West Point. He was made captain of the 1st cavalry 31 Jan. 1861, but resigned on 24 May and entered the Confederate army. He became colonel of the 9th North Carolina Confederate cavalry; in March 1862 was advanced to brigadier-general and on 26 May 1863 to major-general. In 1862 he commanded a brigade and the defenses near Kinston, N. C., and from April to June 1864 the Department of Richmond. He was in command in November 1864 of the subdistrict No. 2 of the department including South Carolina, Georgia, and Florida. Since the close of the war he has been express agent and city marshal of Wilmington, N. C., 1866-7; a farmer in Virginia 1874-8, and latterly a civil engineer in the service of the United States in various river and harbor improvements in Missouri and South Carolina.

Ransom, Thomas Edward Greenfield, American military officer: b. Norwich, Vt., 29 Nov. 1834; d. Rome, Ga., 29 Oct. 1864. He was educated at the Norwich University, studied civil engineering, and settled in Illinois, where he engaged as a civil engineer and a real estate agent. After the outbreak of the Civil War he became a lieutenant-colonel of volunteers in July 1861, and commanded a regiment at Shiloh in April 1862. He was promoted brigadier-general in January 1863; served under General Banks in the Red River expedition; and later joined Sheridan's army, took command of a division just before the capture of Atlanta, 2 Sept. 1864, and died as a result of overtaxing his strength while leading his troops in pursuit of Hood.

Ransom (from Latin, *redemptio*), the sum required to be paid to the captors of a prisoner of war in order to procure his release. The practice of redeeming prisoners of war by a ransom was a very common one not only in ancient times, but in modern times up to the end of the 18th century. As late as 1780 a treaty was concluded between France and Great Britain on the subject of exchange of prisoners, in which the various relations the different ranks bore to each other were specified, together with the sums required to be paid by way of ransom. A French vice-admiral or an English admiral was estimated as of equivalent value in the exchange of

prisoners to 60 sailors or private soldiers, as was also a French marshal or an English field-marshal. Ransom is now exacted only by brigands. Prisoners are generally retained until peace is restored, when they are released without ransom; or they may be exchanged during the progress of hostilities. Officers are frequently released during the war on pledging their word of honor to take no further active share in it.

Ransome, rân'süm, Arthur, English physician: b. Manchester 11 Feb. 1834. He was educated at Trinity College, Dublin, Caius College, Cambridge, and studied medicine in London and Paris. He was lecturer on biology at Cambridge in 1857-61, professor of hygiene at Owens College in 1880-95, became lecturer on phthisis at the College of Physicians in 1890, and is a recognized authority in pulmonary diseases. He has published: 'Stethometry' (1876); 'Causes of Consumption' (1884); 'The Principles of Open Air Treatment of Phthisis and Sanatorium Construction' (1903); etc.

Ranters, a term not in use in the United States, but formerly applied in England to the Primitive Methodists, on account of the enthusiasm and earnestness which characterized their worship. While this is the recent application of the word, it was formerly used in the period of the English Commonwealth to indicate an alleged sect whose practices attracted public reprobation, and which was suppressed by the authorities.

Rantoul, rân'tool, Robert, Jr., American statesman: b. Beverly, Mass., 13 May 1805; d. Washington, D. C., 7 Aug. 1852. His father, who survived him for several years, was long a member of the State legislature. The son was educated at Harvard where he was graduated in 1826. He studied law in Salem, was admitted to the Essex bar in 1827, and for several years practised in Gloucester, which he represented in the legislature 1834-7 and distinguished himself there as a reformer and an advocate of the rights and interests of the common people. He exerted himself for the abolition of capital punishment, and made a report to the legislature on that subject. In 1837 he was appointed a member of the Massachusetts board of education, and gave much time and attention to the advancement of the system of public instruction. In 1843 he became collector of the port of Boston, and in 1845 was made United States district attorney. In 1851 he was elected United States senator to succeed Daniel Webster for the short remainder of his term; and having been prominent among opponents of the extension of slavery, the free-soilers of his district united with the Democrats in electing him to the United States house of representatives the same year. A volume of his speeches and writings with memoir appeared in 1854.

Ranuncula'ceæ, an order of herbs and shrubs. There are about 700 species, widely distributed in cold and temperate climates, and to a very limited extent in warm ones. All are more or less acrid while fresh, but usually lose this property upon being dried. A few have been reputed poisonous, others have been used in medicine, and several for food both for man and animals. The order is, however, chiefly noted for its ornamental species, many of which are widely popular garden flowers. The best

known of these genera are probably *Aquilegia*, *Clematis*, *Anemone*, *Delphinium*, *Helleborus*, *Paeonia*, *Nigella*, *Caltha*, *Aconitum*, *Actaea*, and *Ranunculus*. (See COLUMBINE; ANEMONE; LARKSPUR; PEONY; CLEMATIS; HELLEBORE). The type genus, *Ranunculus*, which includes about 200 species, is also cultivated. The garden or Asiatic *ranunculus* (*R. asiaticus*) is a native of western Asia, and has been cultivated for about 300 years for its brilliant single or double variously colored flowers. The lesser celandine (*R. ficaria*), a European species, is cultivated for its foliage, which is eaten like spinach, and for its tubers, which are served like potatoes. Several species of buttercups, notably *R. acris* and *R. repens*, are well-known weeds in pastures.

Ranz des Vaches, räns dā vāsh, the name of the national air which the herdsmen of the Alps in Switzerland sing or play on an instrument called the Alpenhorn, or horn of the Alps, when they drive out the herds. It consists of a few simple intervals, yet capable of producing a very striking effect in the echoes of the mountains. See NATIONAL HYMNS.

Raoul Rochette, rä-ool rō-shĕt. See ROCHETTE, DÉSIRÉ RAOUL.

Raoult, rä-oo, **François Marie**, French chemist: b. Fournes, Nord, 10 May 1830; d. 1901. He was educated in Paris, where he received the doctorate in physical sciences in 1863. He went to the University of Grenoble to teach chemistry, was made professor in 1870 and dean of the faculty in 1889. In 1890 he was made correspondent of the Academy of Sciences. His researches were first in the field of electro-chemistry; later he turned to the discovery of the freezing-point of a great number of solutions and also the determination of the tension of vapors of volatile liquids.

Raoux, rä-oo, **Jean**, French painter: b. Montpellier 12 June 1677; d. Paris 10 Feb. 1734. He painted history, portraits and genre, and during his lifetime enjoyed a great reputation in France and was even elected to the Academy (1717). He has indeed painted some good landscapes in the style of Claude Lorraine, but his historical pictures are stogy and artificial. His portraits are said to have been good likenesses, and he is chiefly known nowadays for his portraits of fine ladies, on whom he bestowed the false and meretricious graces fashionable in his day. Many of his pictures were engraved.

Rap, familiar in the phrase "not worth a rap," a counterfeit Irish coin of the time of George I., which passed for a half-penny, though not really worth a fourth of that value. There was also a small Swiss coin called "rappen," worth a centime.

Rape, an annual herb (*Brassica napus*) of the order Cruciferae. It is a native of the Old World, where it has long been cultivated for its foliage and its seed, the former of which is an important stock food, the latter, a source of colseseed oil. It resembles the turnip in foliage, but grows taller and lacks the turnip-like root. In America it is not grown for its seed at all, but toward the end of the 19th century became an important soiling and forage crop for sheep, and beef cattle. It is usually sown after mid-

summer upon any good soil, and is especially popular in cool climates because it will stand considerable cold without injury.

Rape, a word derived from German "raffen" and old English "rap," to seize and carry away, and meaning in law the crime of having carnal knowledge of a woman without her consent and by force. This has always been regarded as one of the highest crimes, and is still punished by death in some American States; in others by long terms of imprisonment. In the case of a female who has reached the age of consent, and who is not an idiot, the element of force is essential to constitute the crime of rape. If consent is obtained by the use of threats which convince the woman that it would be useless to resist, it is not necessary to prove actual violence. It has long been established by court decisions in England and America that deception, as when a married woman is deceived into believing that a man not her husband is her husband, does not constitute rape. Within the past 20 years statutes have been passed in England and many of the United States raising the age of consent for girls to 16 years. These laws have been of great service in protecting the young and promoting morality.

Raphael Santi, rä'fā-ĕl sän'tĕ (called by the Italians RAFFAELLE and RAFFAELLO, but generally in his own writings and in the signing of his pictures, RAPHAEL), Italian painter: b. Urbino in Umbria 28 March 1483; d. Rome 6 April 1520. The mountain town of Urbino was the capital of the ancient duchy of the same name, which came to an end in 1626. The castle or palace of the Duke is still a building of extreme interest; and there is evidence that during the lifetime of Frederigo and Guidobaldo—who reigned during the years of Raphael's youth—the palace was one of the most remarkable museums in Italy, being crowded with works of art both of antique and of Renaissance production.

The young Raphael was allowed to devote himself to art the more readily that his father (Giovanni) was himself a painter. It seems that the family had lost property; and there is much in the record concerning Raphael to indicate the existence in his character of traditions of elegant life and that kind of sympathy which comes from ancestral cultivation. At a very early age for a student of art he entered the workshop of Perugino; his possibly earlier studies with Timoteo Viti being of little consequence to his artistic growth. It is asserted that the young man went to Siena, where Pinturicchio was at work; but this is doubtful, and it is only important because there has been so much question about the true influence which at first determined or modified Raphael's career. It was as early as 1504 that he first went to Florence, and the artists who would then have influenced him the most were Leonardo da Vinci and Michelangelo; because while the earlier Florentines would be more immediately recognized by him as painters of the ancient and traditional manner, it is clear from his subsequent history that he was more quick than any other man would have been to adapt himself to the larger conditions of a new world of art. The first absolutely modern painting may be said to have come into existence with Leonardo da

Vinci, although that great master allowed himself but little time to devote to executive work, and has left us almost nothing by which we can judge his full strength. As for Michelangelo (eight years Raphael's senior, and as precocious), his work must have revealed to Raphael the possibilities of magnificent design in which the human body is treated as the principal subject, without important assistance in the way of draperies, backgrounds, or even narrative subject, as a work of art.

The earliest painting which can be ascribed to Raphael with some certainty, is the Marriage or Betrothal of the Virgin (called 'Lo Sposalizio') at the Brera Gallery in Milan. This picture shows the Umbrian feeling, and has many resemblances to the full manner of Perugino, Raphael's master; but it is significant that no serious attempt has been made to dispute the ascription of it to Raphael himself, so great is the resemblance in the peculiar grace of its composition to the more mature works of the younger man. The most important record we have of his earliest stay in Florence, ending with his 25th year, is the Madonna with Saints in the National Gallery, commonly known as the 'Ansidei Madonna,' which, however, is thought to have been painted during a visit which he made to Perugia; and other Madonnas, such as that in the Pitti Palace, called the 'Madonna del Gran Duca,' and the 'Madonna with the Goldfinch' in the Uffizi; as well as a picture in the Louvre Museum at Paris, called 'La Belle Jardinière.' This epoch, however, was one of constant production, and there are many smaller paintings, only less important, than those named above, which may with considerable certainty be given to this period, namely, the years of his life from 20 to 25. It was in 1508 that he went to Rome.

It does not appear that Raphael was sent for directly by the order of Pope Julius II., but he began work there almost immediately on his arrival, and indeed the first of the famous halls in the Vatican which are covered with his paintings was completed, nearly as we see it now, as early as 1511. This room, known as the Camera della Segnatura, or Chamber of the Signature, is a hall roofed with a solid masonry vault, having one large window turned nearly to the north and lighting the room fairly well on bright days. On the west wall is the famous painting known as the 'Disputa del Sacramento,' which should properly be called in English 'The Glory or the Triumph of Religion'; and opposite this to the east is the 'School of Athens.' Over the window is the Parnassus presided over by Apollo; and opposite the window is, in the lunette, the magnificent 'Jurisprudence'; while below this and on either side of the deep niche serving as the recess of a window now condemned, are paintings having to do with the Papal authority in earthly and spiritual things. Similar paintings adorn the dado beneath the great pictures, and the vault itself is covered with work by Raphael's own hand; in fact, lovers of Raphael's painting, considered by itself and without reference to its historical importance, have always found the Camera della Segnatura the most delightful place for the study of the master's individuality. There is every reason to suppose that the greater part of the work here is due to his own touch; the em-

ployment of assistants being much less probable here than in later works.

When this first series of important wall paintings was completed, Raphael was 28 years old, and he had only nine years to live. During those nine years were produced the paintings in the four large rooms in the Vatican adjoining the Camera della Segnatura, and also the decorative frescoes in the Farnesina Palace, the outdoor corridors and vaulted galleries fronting the Cortile di S. Damaso in the Vatican, which are known as the Loggie di Raffaele, and also a great number of easel pictures in oil, portraits, religious pictures sent as presents to the king of France and other foreign princes, and, toward the close of his life, two pictures of peculiar importance in his history, because they have always excited so much general admiration. These are the 'Madonna di San Sisto,' now in the royal collection at Dresden, and 'The Transfiguration,' left unfinished at his death, and now in the picture gallery of the Vatican. Raphael also made some designs, or at least undertook some superintendence as architect, especially in connection with the Church of Saint Peter, and as designer of several palazzi, or stately mansions, in and near Rome. The excavations going on among the ruins of Rome also excited his interest and took up much of his time. He was surrounded by assistant artists who worked with him or for him, under his general direction and also from his studies and under his immediate control. It is now impossible to discriminate between these different ways of work, except by means of the internal evidence of more or less characteristic handling in the painting. Thus it is generally agreed that the large frescoes of the battle at the Milvian bridge and the other paintings in the Stanza di Constantino are almost wholly by the hand of his assistants; while those in the Stanza dell' Incendio and in the Stanza dell' Eliodoro are, though not wholly by the hand of Raphael, his work as to their general designs, as to their composition both in mass and in color, and largely his own creation. The remarkable fact concerning these and the smaller paintings is that they all, except some of those in the Constantine series, belong to that well-known family or class of works which have become familiar to all the European world, as typical pictures by the artist who is generally accepted as the first of religious painters, while at the same time his name is used by artistic reformers as a symbol of the commencement of the decline of art.

His work shows little interest in realization of incident or of action; he is regardless of the impossibilities of the Apostles in long and voluminous robes, and of men in a fishing boat much too small for them—indifferent to the contradictions of the famous picture of 'The Conflagration in the Suburb' ('Incendio del Borgo'), where flames are seen flickering among marble columns and walls of cut stone without anything to feed them; and yet this lack of realism in his designs has never diminished his vast popularity, as the typical painter toward whose work everyone turns when there is mention of Christian religious painting. There is no better instance of the purely artistic quality obtaining full recognition in spite of the absence of those qualities which are generally

RAPHIAEL SANTI.

considered more popular; the main reason for this is in the extraordinarily perfect composition in line and in mass, the figures filling the chosen oblong or the lunette or the circle in so many of his compositions, with absolutely faultless harmony, producing the desired result—a picture of entirely harmonious effect. As a colorist, he is not one of those painters to whom glow and splendor of hue is the important thing, who deem design in color supreme, as do Correggio and the great Venetians from the time of Vivarini to that of Tiepolo; but invested his noble linear compositions with a coloring wholly agreeable, never violent, always satisfactory to the student of sentiment in art, and to the lover of noble composition—those students being more numerous in the world than the lovers of color for its own sake.

Consult: Passavant, 'Rafael und sein Vater'; Eugene Müntz, 'Raphaël, sa vie son Œuvre et son temps' (1881); 'Les Historiens et les Critiques de Raphaël' (1883); Crowe and Cavalcaselle, 'Raphael, his Life and Works' (1882); Bigot, 'Raphael and the Villa Farnesina' (1884).

RUSSELL STURGIS.

Raphael Ware. See MAJOLICA.

Raphall, Morris Jacob. American rabbi and author: b. Stockholm, Sweden, September 1798; d. New York 23 June 1868. In 1812 after receiving rabbinical education at Copenhagen, he went to England to study its language and literature, and after a continental tour spent three years at the University of Giessen, returning to England in 1825. In 1832 he lectured on post-Biblical history in London, in 1834 began a 'Hebrew Review and Magazine of Rabbinical Literature,' which he edited with much scholarship, was associated with D. A. De Sola in a translation of 18 treatises of the 'Mishna,' and with Messrs. De Sola and J. L. Lindenthal in a commentary on Genesis. In 1841 he was elected rabbi of the Birmingham Synagogue and in 1849 was called to the Congregation B'nai Jeshurun of New York, where he remained until his death. In 1855 he published his 'Post-Biblical History of the Jews.' In addition he wrote some learned pamphlets and was a contributor to 'The Jewish Messenger.' His defense of slavery from the biblical standpoint ('The Bible View of Slavery') aroused much controversy in the early days of the Civil War.

Rapha'nia, another name for the disease called ergotism (q.v.).

Raphia, a genus of low African palms with oval, gigantic pinnate leaves, and fruit spikes often weighing from 200 to 300 pounds. See PALMS.

Rapid-fire Guns. See ORDNANCE.

Ra'pier, a sword-like weapon, light, highly tempered, edgeless and finely pointed. It is about three feet in length, and was long a favorite weapon for dueling.

Rapin de Thoyras, ră-păn dē toi-ră, **Paul**, French historian: b. Castres, Languedoc, 1661; d. Wesel, Duchy of Cleves, 1725. He studied at the Protestant Academy of Saumur, and was admitted an advocate in 1679. The revocation of the Edict of Nantes, however, drove him to England in 1686, and subsequently to Holland, where he entered a company of French cadets.

In 1689 he followed the Prince of Orange and distinguished himself at the battle of the Boyne. In 1707 he settled at Wesel and devoted himself to historical composition. His great work, 'L'Histoire d'Angleterre' (1724), was very animated, but impartial, and contains much solid information. The style is clear, the facts are methodically arranged, and he is always careful to cite his authorities. It embraces the period from the invasion of the Romans to the accession of William and Mary, but continuations by other pens were afterward added.

Rapp, rāp (Johann) George, German secretary, founder of the communistic society called Harmonites: b. Iptingen, Württemberg, 1 Nov. 1757; d. Economy, Pa., 7 Aug. 1847. He studied in the village school, became a linen weaver, and even before 1783, when he married, had religious doubts and visions, and dated his "complete surrender" from the year 1782. His peculiar religious ideas were so tinged with political socialism that his followers were persecuted by the German government; and in 1803 he emigrated. In the next year he founded at Harmony, near Pittsburg, a communistic colony, where work, unity, equality, and celibacy were the rule. A new colony, called New Harmony, was founded on the Wabash in Posey County, Ind., in 1815 and was sold to Robert Owen (q.v.) in 1824 when Rapp and his followers returned to Pennsylvania, founding on the Ohio River the town of Economy (q.v.). Consult: Nordhoff, 'Communistic Societies of the United States' (1875); Knortz, 'Die Christlich-kommunistische Kolonie der Rappisten' (1892).

Rapp, Jean, COUNT OF, French general: b. Colmar, Alsace, 27 April 1772; d. near Lorrach, Baden, 8 Nov. 1821. In 1788 he entered the military service, accompanied Desaix during the campaigns in Germany and Egypt, and after Desaix had fallen at Marengo, became aide to Bonaparte. On the breaking out of the war against Austria, in 1805, he accompanied Napoleon, and after the battle of Austerlitz, where he threw the Russian guards into confusion by a bold attack with his cavalry, he was made brigadier-general. For distinguished service done in 1809 he was created a count of the empire, and in 1811 received the cross of grand officer of the Legion of Honor. He was seven years commander of Dantzic, which he defended after the retreat of the French army from Russia, till 1814, during a severe siege of nearly a year, in which he displayed great talent and brilliant courage, and not till all means of defense were exhausted, and he was compelled by famine, did he capitulate. Returning to France in 1814, he was received with distinction by Louis XVIII., and in March 1815, was sent against Napoleon. But when the defection of the whole army rendered all resistance impossible, Rapp also went over to Napoleon, who made him commander of the army of the Rhine. When Louis XVIII. returned a second time to Paris Rapp was pardoned, and retained the command of the 5th division, granted him by Napoleon, till the army was disbanded. After his death appeared the interesting 'Mémoires du General Rapp, écrits par lui-même' (1823). Consult: Spach, 'Le Général Rapp' (1856).

Rapp, Wilhelm, German American journalist: b. Germany 14 July 1828; d. 1 March

1907. He was an active participant in the German revolutionary movement of 1848, and in 1852 emigrated to the United States where he took up journalism as his occupation. He was the successful editor of the 'Turnzeitung' of Philadelphia and Cincinnati, the 'Baltimore Wacchter' (1857-61), (1866-72), and the 'Illinois Staats Zeitung' of Chicago (1861-6), and again from 1891. He wrote 'Recollections of the German Fatherland by a German-American.'

Rappahannock, rāp-a-hān'ōk, a river of Virginia, formed by several small streams which have their rise in the Blue Ridge. It flows east-southeast into the Chesapeake Bay, which it enters about 25 miles below the Potomac. It is about 250 miles long and is navigable over 90 miles from its mouth. The upper part of its course is through a mountainous country, where it is a swiftly flowing stream with many rapids and low falls. At Fredericksburg (q.v.) is a fall which furnishes extensive water power. From Fredericksburg the river becomes a tidal stream, and the broad, long estuary which enters the bay is navigable for the largest steamers. The name of the Rappahannock is associated with many of the events of the Civil War.

Rappahannock Station, Battle of. In the fore part of October 1863 Gen. Lee maneuvered the Army of the Potomac, under Gen. Meade, from the Rappahannock River back to Centreville. Meade resumed the offensive 19 October, and in several encounters pressed Lee back to the Rappahannock, Lee crossing to the south side of the river and disposing his army on both sides of the Orange and Alexandria Railroad, Ewell's corps on the right and A. P. Hill's on the left, with cavalry on both flanks. A part of Ewell's corps was left on the north side of the river at Rappahannock Station, in an intrenched position covering the pontoon-bridge, the railroad bridge having been destroyed. The position was first held by Gen. Hays' brigade and four guns, to which was subsequently added Gen. Hoke's brigade, under Col. A. C. Goodwin. The whole force numbered about 2,000 men. Lee had destroyed the railroad from Bristoe Station to the Rappahannock, a distance of more than 20 miles, and this had to be rebuilt before Meade could follow to the river. It was completed as far as Warrenton Junction on 2 November; supplies were brought up; and on the morning of the 7th Meade advanced to cross the Rappahannock. Gen. French, with the left wing of the army, moved upon Kelly's Ford, five miles below Rappahannock Station, and forced a passage of the river (see KELLY'S FORD, ENGAGEMENTS AT), while the Fifth and Sixth corps, under command of Gen. Sedgwick, moved along the line of the railroad, forming line about midday within one and a half miles of Rappahannock Station, the right of the Fifth corps and the left of the Sixth on the railroad. Skirmishers were thrown forward and the Confederate position reconnoitered, and as soon as it could be ascertained a plan of attack was formed. The works to be carried consisted of two redoubts, connected by a chain of rifle-pits, and a further line of rifle-pits ran from the left redoubt to the river and some distance along it. The Fifth corps was to gain the river bank on the left, and the Sixth on the right, in order to establish artillery on a range

of high ground in front of the works and drive the men from them. The river bank was gained both on the right and left, artillery put in position, and the works shelled, but at dusk no impression had been made, the Confederate guns had not been silenced, nor had the infantry been driven from the works. Gen. Russell, temporarily commanding Wright's division of the Sixth corps, said that he could carry the works by assault, and he was ordered to do it. It was now after dusk; artillery fire was kept up; Russell led parts of Ellmaker's and Upton's brigades, in all 2,117 men and, under a heavy fire of musketry and canister, went over the works in a very few minutes, capturing 1,303 officers and men, the four guns, 1,225 stands of arms, and seven battle-flags. A part of the Fifth corps on the left joined in the assault. Gen. Wright says in his report that this was the first case during the war of an intrenched position being carried on the first assault, and one of Gen. Lee's biographers writes that it was the saddest chapter in the history of the Army of Northern Virginia. Gen. Hays, with nearly 300 of his men and about 130 of Hoke's, escaped. The Union loss was 413 killed and wounded, and six missing. Gen. Lee reports his loss as 6 killed, 39 wounded, and 1,629 captured or missing, some of the missing being probably killed or wounded. Lee now abandoned his design of attacking Gen. French, who had crossed at Kelly's Ford, burned the end of the pontoon-bridge remaining in his possession, the north end of it having been captured by Russell, and fell back during the night to Mountain Run. Gen. Meade crossed the remainder of his army over the Rappahannock on the 8th and moved to Brandy Station, and Lee crossed to the south side of the Rapidan. Consult: 'Official Records,' Vol. XXVI.; Humphreys, 'From Gettysburg to the Rapidan'; the Century Company's 'Battles and Leaders of the Civil War,' Vol. IV.

E. A. CARMAN.

Rap'pists. See HARMONISTS.

Rapto'res, an old name in classification, variously limited, for the predatory birds. See BIRDS OF PREY.

Raratonga, rā-rā-tōng'gā, or **Rarotonga**, an island in the South Pacific Ocean, belonging to the group of Cook Islands (q.v.).

Rarey, John S., American horse tamer: b. Franklin County, Ohio, 1828; d. Cleveland, Ohio, 4 Oct. 1866. In early life he showed a marked fondness for horses and skill in their management, which he later developed by study and close association with them. In 1856 he went to Texas to further his knowledge and upon his return to Ohio engaged in startling exhibitions of his skill. In training or taming the horse his methods were always prompted by a humane spirit, the use of the lash not being resorted to unless in extreme cases. In 1861 he visited England, Russia and other European countries, where his mastery over the wildest steeds amazed and delighted his vast audiences.

Rar'itan, a river in New Jersey, the headwaters of which are in the northern part of the State. It enters Lower New York Bay through Raritan Bay. The latter is really the broad mouth of the Raritan River. The river is navigable to Brunswick Landing, about two miles above New Brunswick.

RASCAL LEAF-CRUMPLER — RASKOLNIKS

Rascal Leaf-crumpler, the leaf-folding caterpillar of a phytid moth injurious to many American fruit-trees, as the apple, cherry, plum (qq.v.), etc.

Rash, an eruption on the skin. The commonest rashes are those of the specific fevers, the crimson rash of measles, the scarlet rash of scarlet fever, the rose-spots of typhoid fever, etc. But there are also numerous eruptions due to disordered states of the body, and apart altogether from any infectious disease; such are nettle-rash and the like.

Rashi, *rā'shē*, properly **Rabbi Salomon-Ben-Isaak**, sometimes erroneously called **Jarchi**, the most famous of French rabbins: b. Troyes about 1040; d. 1105. Entering the Jewish school in Worms he made astonishing progress in ancient languages, philosophy, medicine, and astronomy. His skill in explaining the Holy Scriptures and the Talmud was so remarkable that his contemporaries honored him with the titles of interpreter of the law and prince of interpreters. To satisfy his longings after knowledge he undertook an extensive tour through Italy, Greece, Palestine, Egypt, Persia, and Germany, where he was particular in visiting the towns which possessed learned Jewish schools. The literary treasures thus collected he introduced into his writings, which were received at the time with the greatest enthusiasm, and are still held in high estimation. His most famous work is a commentary on the Pentateuch. He also wrote commentaries on the prophets, the Talmud, and various treatises on miscellaneous subjects. Consult: Zunz, 'Zeitschrift für die Wissenschaft des Judenthums' (1822).

Rask, *räsk*, **Rasmus Christian**, Danish scholar: b. Brendekilde, island of Funen, 22 Nov. 1787; d. Copenhagen 14 Nov. 1832. He studied at the University of Copenhagen, undertook a journey to Sweden and Russia, to increase his acquaintance with the northern languages; and in 1808, after a two years' stay in Iceland became assistant in the academical library of Copenhagen. His fame as a linguist is founded upon such works as 'An Introduction to the Knowledge of the Icelandic or Old Norse Tongue' (1811); an edition of Björnönis Haldorsen's 'Icelandic Dictionary' (1817); 'Instruction in the Anglo-Saxon Tongue'; and 'Researches as to the Origin of the Old Norse or Icelandic.' In 1822 he was appointed professor of literary history at the University of Copenhagen, and subsequently professor of Oriental languages and librarian to the university. During this period he published, among other works, a Spanish Grammar; 'Instruction in the Friesland Tongue'; 'On the Antiquity and Genuineness of the Zendavesta.'

Raskol'niks, or **Rascolnicians**, the name applied collectively to all the dissenters from the orthodox church of Russia, the Greek-Eastern Church. The schism, or *raskol*, was affected at two different times principally; first during the 17th century upon the occasion of the revision of the Testaments by Patriarch Nikou (1652-8) at Moscow; and upon the further revision and the usurpation of secular powers by Peter the Great (1680-1725). On both these occasions great bodies of Raskolniks, refusing to comply with the reforms instituted, left the

church and set up their own religious communities. The general characteristic of all the Raskolniks is conservatism. Differing from the English dissenters who have usually instituted some reform in the creed or the ritual of the body from which they seceded, the Raskolniks secede because they wish to cling to their old customs and beliefs and do not agree to innovations in the orthodox church.

The Raskolniks are of two great classes, each of which is subdivided with endless schisms, and dissenting sects, more or less antagonistic to each other. The Popovtzi, those who have priests, *pops*, in Russian; and the Bezpopovtzi, or those who have no priests. Of these the Bezpopovtzi are the more numerous, the most aggressive and the least conservative.

The Popovtzi have not changed from the beliefs of their old church. They are, for the most, inoffensive and tolerant, and have lately been treated by the state with less severity than before. Under Alexander II. they were allowed to reopen their churches and to build new ones. A certain measure of civic rights was also granted them, together with liberty of religious services. This branch of the Popovtzi, known as the Edinovertzi, have a bishop, who resides at Moscow. Another and much smaller class denounce the Czar and the Established Church and for that reason are treated as dangerous fanatics.

The Bezpopovtzi are much more inimical to the State and the Church. They believe that the present age is one of the anti-Christ, that the authorities to-day, both temporal and spiritual, are his servants and that therefore it would be sin to recognize their authority. They have no priests among themselves, as they believe that every Christian is a priest, in support of which they quote Rev. i. 6, and that churches are unnecessary, since a Christian's body is a temple, based upon 1 Cor. iii. 16. Some of the principal sects of the Bezpopovtzi are: Doukhobors (qq.v.), who in some respects resemble the early Quakers; the Vozdykhantzi, who hold that the world at present is under the reign of the Holy Ghost, whom they worship by prayers and sighing; the Philippines, who observe only two sacraments, the Lord's Supper and Baptism; the Stranniki, who believe the promises of the Lord concerning the Church are already fulfilled and that we are living in the first era of the resurrection; the Molokane and the Obschie (the latter being communists), who reject all external rites; and the anarchistic Khlisti and Skoptzi. These latter two sects are the most feared and hated by the Russian Church and State. The Khlisti are ascetics and practise many fanatical rites under the direction of their prophets and prophetesses, one being that of bodily scourge. The Skoptzi carry the beliefs of the Khlisti to an even greater extreme, mutilating their bodies in horrible manner in the frenzy of their rites. The Khlisti and Skoptzi are treated as criminals and transported to Siberia by the government; other sects of the Bezpopovtzi are denied many of the civil rights enjoyed by the Popovtzi, are closely watched by the police and are much feared by the government.

The Raskolniks, as a whole, are not allowed to worship in public except in their own chapels and churches, which latter must be of distinctly

different appearance from the Eastern-Greek churches; they are not allowed to propagate their beliefs, to open their convents, or to take any part in public processions, either private or official. The number of Raskolniks in Russia has been variously estimated as from five to fifteen millions. According to one writer in 1890 they were thus accounted: the Popovtzi, three millions; the Spiritual Christians, two millions; the Khlisti and Skoptzi seventy-five thousand; other sects of Bezpopovtzi, nine millions. (See RUSSIAN RELIGIONS.) Consult: Gardner, 'Faiths of the World'; Mouravieff, 'History of the Church of Russia' (London, 1842); and any encyclopædia of religious beliefs.

Raso'res, an obsolete, artificial group of birds, the "scratchers," represented by such forms as the fowls, partridges, grouse, pigeons, etc., which were long ago assigned to various natural orders and families.

Raspail, räs-pä-ê, **François Vincent**, French politician and scientist: b. Carpentras 29 Jan. 1794; d. Arcueil 7 Jan. 1878. He went in 1816 to Paris, where he took part in the July revolution of 1830, and later established a journal, 'Le Réformateur,' which in 1834 was suppressed by the government, while in 1835 its editor was condemned to a six months' imprisonment. On 24 Feb. 1848, at the head of a mob, he penetrated to the council chamber of the provisional government, which he compelled forthwith to proclaim the republic. He then founded 'L'Ami du Peuple,' later called 'Démocratie Pacifique,' in which he proclaimed Jacobin principles. On 15 May he was a leader of the invaders of the Palais Bourbon and the hall of the national assembly; for this he was condemned to six years in prison, but in 1855 the sentence was commuted to banishment. He lived in Brussels, but returned to France under the amnesty of 1859, was elected to the Corps Législatif in 1869, retired to private life during the Commune, and from 1876 was a member of the Chamber of Deputies. Among his works were: 'Annales des Sciences d'Observation' (1829-30); 'Recherches Chimiques et Physiques sur le Développement des Tissus Végétaux' (1827); 'Système Nouveau de Physiologie Végétale et de Botanique' (1836); 'Histoire Naturelle des Ammonites' (1842); 'Nouvelles Etudes Scientifiques et Philologiques' (1865); 'Réformes Sociales' (1872).

Raspberry, a general name for those shrubs of the genus *Rubus*, whose fruits separate from the receptacle upon attaining maturity. They are natives of the north temperate zone and are especially numerous in Europe and America. They are characterized by their perennial underground parts, usually biennial spiny stems which bear fruit the second season and then die. Several species are valued for ornamental purposes but the three following are the most important because of their edible fruits, for which the plants are widely cultivated especially in the United States and Canada. The European raspberry (*R. idæus*), which has been cultivated in Europe for several centuries, was among the earliest European fruits introduced into America, but it has not made an equal headway with the next species because it has a very extended period of ripening, and is more adapted to the amateur than to the com-

mercial berry-grower. Its fruits, either red or yellow, are of the best quality, but the plants are considered somewhat tender in northern climates. The American red raspberry (*R. strigosus*) resembles the preceding species in habit and color of fruit, but is rather inferior in quality. This defect, however, is offset by its great productiveness, "cropping" qualities, hardiness and ready adaptability to many conditions. Having been in cultivation for only about half a century, its quick development to the rank of a leading small-fruit augurs still greater possibilities. The black raspberry or blackcap (*R. occidentalis*) is the most important species of its genus, since it is hardy, productive, adaptable to many soils and conditions, and its fruits, being firm, are useful for shipping considerable distances or for evaporating as well as for canning and eating fresh. It was introduced into cultivation in 1832, since when several hundred varieties have been offered for sale.

The red raspberries are propagated by means of suckers, or root-cuttings. The former may appear at any time throughout the growing season; the latter may be made by thrusting a spade deeply into the ground around well established plants and thus severing the roots, each piece of which will produce a new plant. With new or scarce varieties the plants are often dug up, the roots cut in small pieces and rooted under glass. In the field the plants are usually set not less than 5 by 5 feet or 4 by 6 feet apart. In the former case cultivation is given each way; in the latter only one way after the plants are two years old, the rows becoming more or less continuous from the growth of suckers. The former is generally preferred.

The black raspberry does not produce suckers, except at the crown, but the tips of the canes bend over until their tips reach the ground and become covered and develop roots. Other buds near the end may develop short stems which also become rooted. These "tips" are severed for planting, sometimes in autumn but usually in spring, and are set somewhat farther apart than the red varieties. There is a hybrid group of raspberries which propagate by both tips and suckers or root cuttings, usually by the latter. They are supposed to be derived from the black and the American red species, but since they are common in the wild state and are fairly stable, they are often called *R. neglectus*. Several varieties have been widely cultivated. Their fruit ranges from purple, through reds to yellow.

Raspberries succeed best upon deep, moist, but well drained loamy soils; the blacks upon the heavier and the reds upon the lighter. The more retentive of moisture the soil is the better, since the fruit ripens at a time when water is often scarce. Hence the addition of humus is often desirable. It may be most easily obtained in the form of stable manure and green manures, such as clover grown at least one year before planting. The ground should be plowed as deeply as possible without turning up the subsoil, and after harrowing, the plants set. Clean cultivation both ways is usually practised until midsummer when a cover crop of crimson clover or some shallower rooting plant is sown to be turned under the following spring. Sometimes, however, other crops, such as potatoes, carrots,

RASPBERRY VINEGAR—RASSIEUR

beets, etc., which are not tall, are grown between the rows for one or perhaps two years. Wood ashes, muriate of potash, superphosphates, and ground bone are favorite sources of potash and phosphoric acid. With adequate tillage during the summer, spring plowing may be avoided.

The pruning of the red varieties consists in pinching back the shoots during the first season, allowing only about five canes to grow in each stool in after years, avoiding the pinching of shoots unless the soil is very strong and the growth rampant, and cutting out the old canes as soon as they have fruited. The pruning of the blackcaps consists in pinching off the tips as soon as they have reached a height of about 21 inches to make the canes stocky and self-supporting, and shortening in the branches to about 18 inches the following spring. This latter amounts to thinning and should be carefully done.

For market the fruit should never be picked until after the dew has dried and should be shipped to market in small packages. Red raspberries are usually marketed in pint baskets. Black raspberries, specially for canning, are often gathered by jarring the ripe fruits into aprons with boxes attached, the fruit being passed through a fanning mill to blow away the leaves, etc. Generally, however, the picking is done by hand with red raspberries and with both kinds for the best markets.

Among the numerous insects which feed upon the raspberry are two species of cane-boring beetles, *Agilus ruficollis* and *Oberia bimaculata*; wilting of the canes is usually the first indication of their presence, and cutting the injured ones is the only remedy recommended. The snowy tree-cricket (*Ecanthus niveus*, etc.) often lays its eggs in the stems, but is considered to be a beneficial insect otherwise, since its food consists largely of plant-lice. Several caterpillars and other foliage-chewing insects, such as the raspberry saw-fly (*Selandria rubi*), occasionally prove troublesome, and some of the stink-bugs reveal their presence by their disagreeable flavor when inadvertently eaten. General remedies have been recommended for these insects. (See INSECTICIDE.) Several so-called plant diseases have been reported upon the raspberry. The orange rust has never been successfully combated except by digging out and burning plants attacked by it; and anthracnose has been held in check by spraying. (See FUNGICIDE.)

Consult: Bailey, 'Cyclopedia of American Horticulture' (New York, 1900-2); Card, 'Bush-Fruits' (New York, 1899); Saunders, 'Insects Injurious to Fruits' (Philadelphia, 1889); Smith, 'Economic Entomology' (Philadelphia, 1896;) and numerous bulletins of Agricultural Experiment Stations.

M. G. KAINS,
Crop Expert.

Raspberry Vinegar, a refreshing summer beverage and cooling drink for invalids, composed of raspberry juice, vinegar, and sugar.

Raspe, răs'pê, Rudolph Eric, German mineralogist and author: b. Hanover 1737; d. Muckross, Donegal, Ireland, 1794. In 1767 he was made professor in the Collegium Carolinum of Cassel, and curator of the Landgrave's museum of coins and antiquities. He published

at this time papers on mineralogy and geology. In 1775 he went to England, where he was variously employed, generally as a mining expert. He published in 1785 'Baron Münchhausen's Narrative of his Marvelous Travels and Campaigns in Russia,' founded in part on the hunting stories of one Baron von Münchhausen, of Hanover. His work appears as chapters ii.-vi. of the later Münchhausen. See MÜNCHHAUSEN.

Rassam, răs-săm', Hormuzd, Turkish archaeologist: b. Mosul, Asiatic Turkey, 1826. Having formed the acquaintance of Layard (q.v.) in 1845 when the latter was beginning his explorations of the remains of Nineveh, Rassam accompanied him on his return to London and entered Oxford University, after which he went with Layard on several archaeological expeditions. In 1851 Rassam, upon commission from the British Museum, collected for that institution a number of specimens of Assyrian art, particularly a series of sculptures representing the lion chase. In 1864 the British government despatched him on a mission to Abyssinia to secure from King Theodore the release of their consul, Mr. Cameron, and others held prisoners; but he was himself taken prisoner and held until the defeat of Theodore's army by Sir R. Napier in 1868. After 1876 he resumed his collections for the British Museum, the most notable of which were the bronze gates of Balawat, dating from Shalmanezar II., 858-824 B.C., and the "Abu-Habba tablet," from the temple of the sun-god in Sippar, recording the restoration of the temple by Nabu-apal-iddin. The British Museum was also enriched by his discovery of 5,000 tablets representing, probably, the library of an ancient Babylonish king. Rassam published a 'Narrative of the British Mission to Theodore' (1869); 'Asshur and the Land of Nimrod' (1897).

Rasse, răs, a small arboreal civet (*Viverricula malaccensis*), which is widely distributed in southeastern Asia and the Malayan islands; and long ago became naturalized in Madagascar. It is slender, agile in tree-climbing, has no erectile mane, and lives in holes in rocky and brushy districts. In confinement it is easily tamed and feeds on small animals, which it catches with cat-like dexterity. Hence it is often kept in houses in the East as a rat-ter, and also for the sake of its civet, which is artificially removed from the glands. It is a handsome little animal, spotted with blackish on a gray ground, and with a long black-ringed tail. Consult: Blanford, Jerdon, Tennent, and other authorities on Oriental zoology.

Rasselas, răs'ê-lăs, a philosophical romance by Dr. Samuel Johnson, published in 1759. Though little read at present it was in the 18th century the most popular of its author's works and was translated into many modern languages. It professes to relate the story of Rasselas, prince of Abyssinia, who with his brothers and sisters inhabits a Happy Valley secluded from the outside world.

Rassieur, răs'sê-êr, Leo, American lawyer: b. Waden, Prussia, 19 April 1844. He was graduated at the Saint Louis Central High School in 1860. During the Civil War he volunteered as a private, and in 1865 was raised to the rank of major. In 1867 he was admit-

ted to the Saint Louis bar and after holding office in the public schools was elected judge of the Probate Court (1899). In 1900 he was elected commander-in-chief of the Grand Army of the Republic.

Rastatt, răs'tăt, or **Rastadt**, a town of Baden, Germany, on the river Murg, about 4 miles from the Rhine and about 15 miles southwest of Karlsruhe. It was formerly a fortress of the first rank, but in 1892 the fortifications were dismantled. The town has manufactures of lace, tobacco and cigars. Population in 1900, 13,941. Rastatt was the scene of two diplomatic congresses in the 18th century. The first congress of Rastatt met in 1713 to arrange terms of peace between the emperor and France, then still engaged in the war of the Spanish Succession. Peace was concluded 7 March 1714. In accordance with the terms of the treaty France gave up possession of the towns of Kehl, Freiburg and Breisach, and the electors of Cologne and Bavaria were reinstated in power. The terms of the treaty of Utrecht (q.v.) were ratified. The second congress of Rastatt met in 1797 for the purpose of terminating hostilities between France and the Empire. After negotiations had been prolonged for more than a year, war broke out again between France and the allies and the congress suspended its sessions (April 1799). As the French representatives, Roberjot, Bonnier and Debry left the city on the evening of 28 April, they were set upon by a company of hussars wearing the Austrian uniform and the first two were murdered. Many attempts have been made to fix the responsibility for the deed. Some have ascribed the crime to the Austrian government which was desirous of obtaining certain papers in the possession of the ambassadors; others maintain that the murderers were French émigrés, while others still assert that the act was instigated by Napoleon and other leaders of the war party in France for the purpose of exasperating the French people against Austria.

Rat, any of several large rodents of the mouse family (see **MOUSE**), especially two species of "house-rats" now habituated to civilization in all parts of the world. The black rat (*Mus rattus*) is of light and slender build, about seven inches in length, usually of a bluish black color, but sometimes grayish, and has quite large thin ears. The brown rat (*M. decumanus*) or Norway rat, as it is often inappropriately styled, is much heavier and larger, with short rounded ears and a dull brown color. Both species are believed to be natives of China, but the black rat was abundant in Europe at least as early as the 13th century. The brown rat migrated from Western China, entering Russia in great numbers in 1727, and from there quickly spreading over Europe, which was fully occupied by it by the middle of the 18th century. By its greater fecundity and ferocity it quickly overcame the black rat, which it has now replaced in most parts. It infested ships and by this means has been carried to all parts of the world. Its wonderful capacity for increase (from 20 to 50 annually), its boldness, tough, elastic constitution and adaptable nature, make it everywhere dominant, and its omnivorous habits, voracity and destructiveness frequently lead it to become a source of great

annoyance, loss and disease about human habitations. The ferocity of this species when brought to bay is well known; and when driven by hunger it is so ravenous that neglected babies have been known to be killed and eaten by them, and a few cases are recorded where even able-bodied men have suffered a like fate when attacked by hordes of rats. They are also agents in the spread of disease, particularly bubonic plague and trichinosis. Against their many faults may be set the solitary virtue that they serve a useful purpose as scavengers in the city sewers, etc. The albino and black and white pied rats sold for pets by bird dealers are derived from the black rat, which has a far milder disposition.

Rat-kangaroo. See **KANGAROO**.

Rat Portage, Canada, town and port of entry, Ontario, at the outlet of the Lake of the Woods, and on the Canadian Pacific Railway, 130 miles by rail east of Winnipeg. It is the chief town of the Rainy River District, and the distributing centre for the neighboring gold mines. The Winnipeg River with a fall of 16 feet from the lake, furnishes inexhaustible water power for sawmills, flour-mills, and other industrial establishments. The neighboring lake fisheries, especially of sturgeon, are valuable. Pop. (1891) 1,806; (1901) 5,202.

Rat-tail, one of the pelagic, cod-like fishes of the genus *Macrourus*, specifically *Macrourus bairdi* of the coast-waters of the eastern United States.

Ra'ta, any of several New Zealand trees of an Australasian group of the myrtle family which includes the local ironwoods. Foremost among them is *Metrosideros robusta*, a tall strong tree, of very hard wood, used by the natives for making their war-clubs, and by the colonists in cabinet-work and in ship-building. Another species (*M. florida*) is a huge climber. These trees have very showy flowers, usually red, and characterized by many tall erect stamens; and several species of the genus are cultivated as ornamental shrubs, and have been acclimatized in other parts of the world. One (*M. tormentosa*) is known in New Zealand as "fire-tree."

Ratafia, răt-a-fē'a, a French cordial flavored with fruits; a general name for any liquor flavored with fruit syrups.

Rat'any, or **Rhatany**. See **RATTANY**.

Ra'tel, a South African badger (*Mellivora capensis*), rather larger than the common European or American badger, which lives in burrows in open districts. It differs from the Indian honey-badger (q.v.) mainly in the presence of a distinct white line along its sides, from the nose to the hocks, separating the black underparts from the blanket-like gray of the back.

Rath'bone Sisters, Order of. See **ORDERS, RELIGIOUS**.

Ratichius, rā-tīk'ī-ūs. See **RATKE, WOLF-GANG**.

Ratification, in law, the confirmation, sanction or approval given by a person who has arrived at his majority to acts done by him during his minority. It has the effect of giving validity to such acts as would be otherwise voidable. "An act performed by one for another,

RATIO — RATIONALISM

is adopted as his own act when by him ratified. Ratifications are either express or implied. The former are made in express and direct terms of assent; the latter are such as the law permits for the acts of the principals."

Ratio (from the Latin *ratio*, meaning reckoning, calculation), in mathematics, the measure of the relation which one quantity bears to another of the same kind; that is, the number of times that one quantity contains another regarded as a standard. This is found by dividing the one by the other. The quotient or ratio thus obtained is the proper measure of the relation of the two quantities. Some mathematicians define the ratio of one quantity to another as the quotient of the first quantity divided by the second, and others define it as the quotient of the second quantity divided by the first. The operation of finding a ratio is purely numerical, and the resulting ratio is consequently an abstract number. Ratios are known as *prime* or *ultimate*, according as the ratio of the variable quantities is receding from or approaching to the ratio of the constant quantities. Proportion is the relation of equality subsisting between two ratios. See MATHEMATICS; PROPORTION.

Ration, in the army and navy, is the allowance of provisions given to each officer, non-commissioned officer, soldier, and sailor. In the American army the ordinary ration is commonly supplemented by additional articles bought with what is known as "the company fund," money derived from certain allowances made to the soldiers. The American troops and sailors are better fed than any in the world, whether in camp or war.

Rationalism, in its more general signification, denotes a tendency or attitude of thought, either on the part of an individual or an age, to demand that prevailing beliefs, customs, and institutions shall be subjected to critical examination, and be required to justify themselves before the court of reason. In its more specific sense, the term refers to the doctrines of a particular school of philosophical thinkers, which flourished mainly in France and Germany during the 17th and 18th centuries, and which regarded reason as the only source of certain knowledge, and the only test of truth.

In the general and more popular use of the term, rationalism is equivalent to a demand for a reasonable explanation in scientific terms. The rise of rationalism is thus in many respects identical with the development of the scientific spirit of inquiry. As such, it is opposed to mysticism and supernaturalism. Lecky, in his 'History of the Rise and Influence of Rationalism in Europe,' explains the word as follows: "By the spirit of rationalism, I understand not any class of definite doctrines or criticisms, but rather a certain cast of thought, or bias of reasoning, which has during the last three centuries gained a marked ascendancy in Europe. . . . At present, it will be sufficient to say, that it leads men on all occasions to subordinate dogmatic theology to the dictates of reason and of conscience, and, as a necessary consequence, greatly to restrict its influence upon life. It predisposes men, in history, to attribute all kinds of phenomena to natural rather than miraculous causes: in theology, to esteem succeeding systems the expressions of the wants

and aspirations of that religious sentiment which is planted in all men; and, in ethics, to regard as duties only those which conscience reveals to be such." Between the claims of revealed religion and the spirit of rationalism the conflict has been especially sharp and long-continued. This opposition shows itself even before the birth of Christianity in almost all of the older religions. In Greece, for example, where religion was only to a very slight extent embodied in dogmas, the philosophers were nevertheless frequently charged with atheism, or with perverting and destroying the national religion through their rationalistic teachings. With the establishment of the Christian Church, the doctrines of religion were explicitly declared to be above reason, and to rest upon a higher authority than human reason could afford. Nevertheless, from time to time there arose thinkers within the Church itself who strove to reduce the theological doctrines to a rationalistic basis, interpreting them in such a way as to minimize or destroy the supernaturalistic elements which they contained. Of these mediæval rationalists Abelard (q.v.), 1079-1142, is perhaps the most famous. It was not until the 18th century, however, that rationalism became strong enough and bold enough to make open war upon the prevailing theological beliefs and doctrines. This century was called the age of enlightenment, and in it the demand arose on all sides that everything should be explained in terms of the clear and distinct ideas of reason, that mysteries and superstitions should be abolished, that the authority of church and state should be limited and subordinated to the principles of reason and the interest of the individual members of society. The Deistic movement in England is especially noteworthy as maintaining the right of individual free thought in matters of religion, and as attacking the abuses and absurdities in the existing theological creeds. Lord Herbert of Cherbury and John Locke may be regarded as forerunners of English Deism (q.v.). The best known representatives of the movement are John Toland (1670-1729), Anthony Collins (1676-1729), Matthew Tindal (1657-1733), Thomas Chubb (1679-1747), and Thomas Morgan. The influence of this movement was felt throughout Europe. In Voltaire it found a spokesman of extraordinary literary power who had also the courage to carry its principles to its logical conclusions.

The spirit of rationalism, in so far as it represents the claims of free scientific inquiry, may be said to have already won its triumph. This triumph too, it must be admitted, was largely the result of the enthusiastic zeal of the apostles of the enlightenment. Nevertheless, the spirit of modern inquiry has been profoundly modified in many respects during the 19th century. In the first place, it has lost the narrowness and hardness that it necessarily exhibited so long as a large share of its strength was expended in negative criticism and in making war upon prevailing creeds and institutions. In addition, it has been transformed by the historical and evolutionary conceptions that have become dominant in every field of inquiry, leading men's thoughts, to problems of genesis and origin, and so to understand and sympathize with much that appeared absurd and unmeaning to the older rationalists. The 18th century

rationalists regarded the world as static; they looked at each thing as it actually stood before them in their own day, and judged it by the unchanging standard that each individual was supposed to possess in the clear and distinct ideas of his own individual reason. The historical point of view has brought with it a broader conception of reason and what is rational: it has taught us that it is only in the light of its origin and function that a thing can properly be judged, and that, accordingly, there may be a truer rationality in historical creeds, beliefs, and institutions than in the self-confidence of the individual of clear and distinct ideas who ventures to criticize what he does not understand.

The philosophical doctrine known as rationalism owes its origin to Descartes (1596-1650), and has its home mainly in France and Germany, while empiricism (q.v.), the theory to which it was directly opposed, flourished mainly in England. The rationalistic school take mathematical demonstration as the perfect type of knowledge, and seek to model their procedure in all fields of inquiry on what they assumed to be its method. From the chaotic and contradictory material supplied by sense-perception they believed that real knowledge, science, could not be attained. Mathematics, however, reaches its results in independence of such a source. It begins with fundamental principles and conceptions which are self-evident, and proceeds by means of logical analysis and reasoning to show what further results are necessarily involved and implied in the starting-point. Now, the rationalistic thinkers maintain that what has been achieved in this particular science may be carried out universally by the application of the same method. That is, the true method of knowledge consists in first discovering by analysis the fundamental truths that lie at the basis of all thinking. These truths are not derived from experience, but, like the mathematical axioms and first principles, are native to the mind, innate ideas or *a priori* truths that are the starting-points for all demonstration and all science. When these are once discovered, it is the further task of philosophy to deduce by logical reasoning the further results that follow from them. In this way the rationalists supposed that it was possible to arrive at conclusions in philosophy that are as demonstrably certain as the propositions of geometry.

Besides Descartes, the chief representatives of rationalism are Spinoza (1632-77), who adopted the geometrical form of proof in his chief work, the 'Ethics'; Leibnitz (1646-1715), and Christian Wolff (1679-1754). The last mentioned philosopher, though the least original, exercised a great influence over the thought of Germany by his terminology, and by the systematic way in which he divided the field of philosophy into the so-called sciences of rational cosmology or physics, rational psychology, and rational theology. The first of these seeks to furnish demonstrative proof of the fundamental nature of the physical universe; for example, that it is limited in space, had a beginning in time, made up of indivisible parts, etc. Rational psychology sets out from the conception of the soul as a spiritual substance and attempts to prove that it necessarily follows as a result of this initial conception, that the soul is simple, indivis-

ible, indestructible, and therefore immortal, and moreover, that it possesses certain faculties, such as those of representation, desire, as essential to its true nature. In like manner, rational theology dealt in the same *a priori* and deductive way with the various proofs for the existence and attributes of God. This was the form of rationalism in which Kant was educated, and it is against these so-called rationalistic sciences that he directs his attack in the dialectic of the 'Critique of Pure Reason.' The criticism of Kant was so penetrating and thorough-going that it annihilated at a blow the claims of rationalism. It did this by pointing out, in terms that could neither be mistaken nor denied, the falsity of the assumptions upon which this philosophical theory rests. Kant (q.v.) is thus the destroyer and finisher of rationalism.

Professor of Philosophy, Cornell University.

Rationalists. See RELIGIOUS SECTS.

Ratisbon, rät's-bön (**Regensburg**, rä'gëns-boorg), Bavaria, Germany, 82 miles by rail northeast of Munich, partakes of the artistic tendencies of the latter. Chief among its public buildings and institutions are the Gothic cathedral, library, art-gallery, seminaries and glass-staining factory. Trade, facilitated by its favorable position on the Danube, is considerable. Ratisbon suffered much from bombardments at various periods of its history, especially in 1809, when it was stormed by the French. Pop. (1900) 45,426.

Ratitæ, rā-ti'tē, a group of birds broadly characterized as having a non-carinate sternum and little or no power of flight. The group originally was one of the two grand divisions of *Aves*, embracing all those whose sternum had no keel, as opposed to *Carinata* (q.v.); but this character alone will not define the *Ratitæ* as at present constituted by the researches of Gadow and accepted by ornithologists generally. Its place is as a subdivision of the *Neornithes* (q.v.) co-ordinate with the *Odontolæ* (*hesperornis*, etc.) and the *Carinata*; and the sum of many anatomical peculiarities distinguishes the group, which consists of the ostriches, cassowaries, kiwis, moas, rocs (*Æpyornis*), and perhaps some of the fossil birds of Patagonia whose relationships are not yet perfectly clear. The conspicuous feature of all these is the rudimentary condition of the wings, so that the ratites are well designated flightless birds, the disappearance of the tail, and the great prominence of the functions and development of the legs and feet. These features are believed to be the result of changes, very long continued, from ancestors which possessed the power of flight and have lost it by disuse, and in adaptation to life upon

plains and deserts. Consult: Evans, 'Birds' (1900); Newton, 'Dictionary of Birds' (1893-96); Stejneger, 'Standard Natural History,' Vol. IV. (1885).

Ratke, rät'kē, **Wolfgang** (better known by his Latinized name of RATICHUS), German educator: b. Wilster, Holstein, 18 Oct. 1571; d. Erfurt 27 April 1635. He was trained in the Johanneum at Hamburg and the University of Rostock. Between 1603 and 1611 he lived in Holland and was the inaugurator of a new plan of school reform. The essence of his system was to discard the old memory and rote method of teaching children; to interest them, by presenting things to their observation, and afterwards, names—a reversal of the method then in vogue; to teach them their mother tongue first and thence proceed to foreign languages. At first he met with little success in propagating his views. In 1618, however, he settled at Köthen, Anhalt, and Prince Ludwig von Anhalt furnished him with the means of opening a school to be conducted according to his own ideas. Owing to certain faults of his own, as well as to the unsettled religious condition of Germany at that time he was obliged to leave Köthen and settled at Magdeburg in 1721. Here he made a second failure and afterward led a somewhat wandering life. But his influence upon his contemporaries and posterity was much greater than would be supposed from the failure of his own attempts to put his plan in practice. Consult: Krause, 'Wolfgang Ratke, im Licht seiner und seiner Zeitgenossen Briefe' (1872); Schumann, 'Die echte Methode W. Ratkes' (1876).

Raton, ra-tōn', N. M., city, county-seat of Colfax County; on the Atchison, Topeka & Santa Fé railroad; about 130 miles northeast of Santa Fé and eight miles south of the northern boundary of the Territory. In the vicinity are extensive coal fields. It is the commercial and industrial centre of a large region devoted chiefly to farming and stock raising. It has railroad shops, stock yards, grain elevators, wholesale houses, and brick and lumber yards. Pop. (1890) 1,255; (1900) 3,540.

Rattan, a product of *Calamus rotang*, a scandent palm of Ceylon, but also found in India and Burma. While this species furnishes the best commercial rattan, there are nearly 200 species in this genus, inhabiting tropical and subtropical Asia, Africa, and Australia. The most important species other than the above are *C. rudentum*, *C. pachystemonus*, and *C. radiatus*, abounding throughout the damp forests of Ceylon up to 3,500 feet elevation. *C. rotang*, and the first two species named above are manufactured into a great variety of useful articles such as baskets, chairs, the hoods of carts, and when split into strips, can be twisted into cordage of great strength. *C. rotang* is often used in eastern countries for rope bridges, or, used entire, is stretched across rivers as the supports of suspension bridges; and is also employed for the manufacture of Malacca canes. In China rattan is a favorite material for cordage, and the material also enters into the manufacture of umbrella handles and ribs, and as a substitute for whalebone. The cane is used for saddlery and harness and for wickerwork helmets, said to be sword-proof. The two smaller species (*C.*

pachystemonus and *C. radiatus*) are largely employed in the manufacture of baskets for the Ceylon tea gardens, used in picking the tea leaves. *C. radiatus* supplies the material for chair bottoms, being split into thin strips. In fact the many uses of rattan in eastern countries are almost nameless. In the United States rattan is largely used for manufacturing chairs and other furniture, for chair-seating, baby-carriage bodies, baskets, floor mattings, brooms, corset-stays, whips, and many other uses of minor importance. The "reed" used in raffia fancy-basket manufacture, a recent fad in this country, is the split inner portion of rattan dressed in cylindrical form like the true reeds. See also FIBRE.

CHAS. RICHARDS DODGE,
U. S. Government Fibre Expert.

Rat'tany, or **Rhatany**, a coarse plant of the genus *Krameria* and order *Polygalce*, native to the Andean table-lands. The roots have medicinal value as an astringent, and serve, especially in Portugal, to color wines ruby-red. This property is due to the presence of ratanhia tannic-acid. The root-bark also contains an almost insoluble free red substance called ratanhia-red.

Rattazzi, rät-tät'sē, **Marie Studolmine de Solms**, French novelist: b. Waterford, Ireland, 1833; d. Paris February 1902. She was the daughter of Sir Thomas Wyse, British ambassador to Greece, and Letitia, eldest daughter of Lucien Bonaparte. She was married to Urbano Rattazzi (q.v.) in 1863, and to M. de Rute in 1877. Twice, in 1852 and 1864, she was exiled. She wrote much in prose and verse, and was a prominent figure in the politics and society of the Second Empire salons. Among her works were: 'Les Mariages d'une Creole' (1864); 'Si j'étais Reine' (1868); 'L'Aventurier des Colonies' (1885), a drama; and the volume of tales, 'Enigme sans Clef' (1894).

Rattazzi, **Urbano**, Italian statesman: b. Alessandria 29 June 1810; d. Frosinone 5 June 1873. He studied law at Turin and, after practising with marked success at the capital and at Casale, was elected a member of the Sardinian parliament from his native town in 1848. He allied himself with the liberal party and attained such speedy recognition that in August he was made minister of public instruction. He left office after a few days, but in December of the same year assumed the portfolio of the interior under Gioberti, exchanging it later for that of justice. On the fall of the Gioberti ministry, Rattazzi was entrusted with the formation of a new cabinet (February 1849) but the disaster of Novara in the following month robbed him of power. From democrat he now turned moderate liberal and formed the party of the left centre whose coalition with the right centre under Cavour (q.v.), the so-called "connubio," brought about the fall of the d'Azeglio cabinet in November 1852 and the organization of a new ministry by Cavour. Rattazzi gave up the presidency of the Chamber to become in 1853 minister of justice, and later, of the interior, and in the second capacity precipitated a bitter struggle with the clerical party by the introduction of a law providing for the partial secularization of church property and restricting the influence of the religious associations. He left the cabinet in 1858 but in

RATTIGAN — RATTLESNAKE

July of the following year, after Villafranca, succeeded Cavour as head of the cabinet, only to give place to his predecessor within six months. He opposed the cession of Savoy and Nice to France, became president of the lower chamber in the first Italian parliament and in March 1862 succeeded Ricosoli in the government, retaining for himself the portfolios of foreign affairs and of the interior. His course in checking the patriotic agitation against the Austrians in Lombardy and the papal rule in Rome, brought him great unpopularity and in December 1862 he retired from office. Once more he succeeded Ricosoli, as premier, in 1867, but again had to yield to the storm of popular anger aroused by his hostile attitude toward Garibaldi (q.v.) and he resigned in October of the same year.

Rattigan, Sir William Henry, English jurist: b. Delhi, British India, 4 Sept. 1842. He was educated at King's College, London; admitted to the bar in 1873; served four times as judge of the chief court of Punjab; was additional member of the supreme legislative council of India 1892-3, and member of the Punjab legislative council 1898-9. In 1895 he was knighted and since 1901 he has been member of Parliament for northeast Lanarks. He has published 'De Jure Personarum' (1873); 'The Science of Jurisprudence' (3d ed. 1892); 'Private International Law' (1895); etc.

Rattlesnake, a distinctively American group of poisonous serpents characterized by a peculiar horny rattle appended to the tail. They belong to the suborder *Solenoglypha*, all the members of which are poisonous and have the fang-bearing maxillary bones erectile. To this suborder belong the Old World families of *Viperidæ* (vipers) and the *Crotalidæ*, or pit-vipers, which inhabit both hemispheres. The latter have the maxillary bone deeply excavated to lodge a sensory pit of unknown function opening on the face between the eye and nostril. There are two subfamilies, the *Lachesinæ*, which have no caudal rattle, and the *Crotalinæ*, or rattlesnakes. The former includes the copperhead, water moccasin and fer-de-lance (qq.v.), the banana snake, whose presence in bunches of this fruit so often causes consternation on fruit ships and in storage houses, and numerous others of tropical America, India, and the Malay Islands.

The *Crotalinæ*, or rattlesnakes, represent the highest type of serpent development and specialization. The caudal rattle, from which they take their name, consists of a series of dry horny epidermal rings so loosely fitted that any movement causes them to knock together with a sharp rustling rattle. They are formed in the following manner: Several of the terminal vertebrae of the tail are coalesced to form a dilated vertically enlarged plate. This is covered with a thick vascular skin so cut by an annular constriction as to form a larger anterior, and a smaller posterior knob, which together may be considered to be a mold on which the joints of the rattle are formed. The epidermis covering this region is especially thick, and in the young snake forms a button and ring, which are the only indications of the rattle. When the snake sloughs, the horny covering is loosened here as elsewhere and a new

layer is formed beneath it; but instead of being cast off with the rest of the epidermis, the open end of the old horny ring fits over and by its elasticity clasps the new knob at the end of the tail, and by this means remains attached. With each subsequent molt a new ring and button are added, the latter serving to hold its predecessor in the series, and which continue to increase in size with the growth of the snake and its caudal knob. As well-fed snakes may slough 3 or 4 times a year, and as the rings sooner or later become worn out and detached, it is evident that the popular belief that the number of joints in the rattle indicate the years of the snake's age is unfounded. Rattles of more than 12 joints are rare, but one having 21 is known. When the snakes are irritated or angry, the end of the tail is more or less elevated and vibrated rapidly, producing a sound audible at a distance of 30 or 40 paces. Many snakes, both venomous and innocuous, have this habit of vibrating the tip of the tail when angry and many have a hard horny spur or cap at its end, but no others retain this through a succession of molts. Many fantastic theories have been proposed in explanation of the utility of the rattle, but it is probably little more than a recognition character, which helps to bring the sexes together and to segregate the species. However, it is probable that its sounding formerly saved the lives of many rattlesnakes by warning large animals acquainted with their deadly powers from the vicinity, but since the advent of the white man it has had a precisely opposite result.

Poison.—The venom apparatus of the rattlesnakes is the most complete and effective contrivance imaginable for injecting the poisonous fluid into the circulation of a victim. The maxillary bones are very short and are freely movable on an articulation with the prefrontals. Upon them are attached the venom fangs at such an angle that with the movements of the maxillary they may be depressed in a fold of mucous membrane or erected vertically in the very front of the mouth in a most effective position for striking. The tooth substance of the fang is folded into a tubular form, with an opening at the base to receive the end of the venom duct and another near the front face of the needle-pointed tip. Behind the functional fang, which may be nearly an inch long in large snakes, is a succession of smaller reserve fangs, which become functional in order as their predecessors are lost. The venom gland, which corresponds to the parotid salivary gland of other animals, is situated on the cheek and has a duct running to a sinus at the base of the fang. All of the muscles and other parts are so arranged that the same movements that open the mouth and press the horizontal pterygoid bones forward to erect the maxillaries with their fangs, also compress the poison gland and squeeze out its secretion. Cope describes the biting movement as threefold. "First, there is the spring of the body, which never exceeds two thirds of its length; second, the bite proper, caused by the seizing of the jaws; and, third, the clutch with the fangs themselves, which are moved freely backward and forward." This movement of the fangs may be easily seen by holding a rattlesnake so that it cannot strike, when drops

RATTLESNAKE

of the pale yellow venom may be seen to fall from their tips and are sometimes blown from the mouth by forcible expirations. The active principles of the venom are several soluble proteids, one of which has a disorganizing effect on tissues with which it comes in contact and another is a powerful heart and respiratory depressor. The immediate effect of a bite is severe burning pain followed in 10 or 15 minutes by prostration, with dizziness, vomiting, and cold sweats; the heart action is very feeble and the pupil dilated. This condition gives way in from 12 to 15 hours to one of fever and difficult respiration, while the part affected becomes greatly swollen and the neighborhood of the wound suppurates. Death may occur in either of these stages or as a result of secondary gangrene. Treatment to be effective must be prompt and thorough. A ligature should be applied above the wound and the latter enlarged with a clean knife until the blood flows freely. Permanganate of potash, bleaching powder, chromic acid, silver nitrate or other substances, which render the active albumens insoluble should be applied to the wound. Small and frequent doses of whiskey, strychnine or ammonia should be administered as a stimulant, but an excess of alcohol may increase the depression. Every effort should be made to press or draw the poison from the wound before the ligature is removed, but sucking with the mouth is always dangerous.

Species of Rattlesnake.—Of rattlesnakes three species of *Sistrurus* and 16 of *Crotalus* have been described, three of which are South and Central and the rest North American. None occur in the West Indies. The species of *Sistrurus* are small snakes with the snout and frontal region of the head covered with large plates. The ground rattlesnake or massasauga (*S. catenatus*) is found on low prairie lands from Ohio and Minnesota southward, but is now rare or exterminated in all settled parts. It reaches a length of three feet and is not considered especially dangerous. About six young are born alive in September; and this is one of the snakes for which it is pretty clearly established that the newly hatched young seek refuge from danger in the mouth and gullet of the mother. A related species (*S. miliarius*) is found in the Southern States.

In the genus *Crotalus* the entire top of the head is covered with small scales. The common or banded rattlesnake (*C. horridus*) was formerly abundant throughout the entire eastern United States, and it is the only species found in the New England and Middle States, but has been largely exterminated by the white man and his companion, the hog. The latter in roaming the woods in search of mast, etc., never fails to kill and devour the rattlesnake whenever possible. It is commonly believed that the hog is immune to snake-bites, but the truth is that the poison is dissipated in the thick skin and layer of subcutaneous fat, and never reaches the vascular tissues beneath. This rattlesnake prefers sparsely wooded rocky ridges with sunny exposures and in such localities is still common in the mountains from Pennsylvania to Tennessee. It is a sluggish and generally peaceful creature and seldom bites, except to secure food, unless it be trod upon or startled. When about to strike it coils with the head in the middle and

elevated and the rattle sounding, delivers a lightning-like blow and immediately re-coils or slowly retreats. It seldom attacks without provocation, or follows a foe. All kinds of small mammals, especially mice, and occasionally birds are its food, and it drinks water freely. The cold months of the year are passed in hibernation and frequently large numbers of these snakes congregate in caves or beneath rocks for this purpose. Mating takes place in the early summer and about September from six to nine young about nine inches long are born alive. A length of five feet is sometimes attained, but ordinary examples seldom exceed four. Among the natural enemies of the rattlesnake are the king-snake and blacksnake, birds of prey and herons. The diamond or water rattlesnake (*C. adamanteus*) reaches a length of upward of eight feet and a circumference of fifteen inches, and is not only the largest of the rattlesnakes, but the bulkiest of all poisonous snakes, being exceeded in length only by the slender snake-eating cobra. It inhabits the Southern States and is particularly abundant on the Florida Keys. Except that it prefers the vicinity of water, in which it swims freely, its habits are much like those of the common species. Because of its great size, and the large amount of venom which it secretes, this is an extremely dangerous reptile; it is also sometimes inclined to be aggressive. The prairie rattlesnake (*C. confluentus*) inhabits most parts of the western plains and deserts, and is exceedingly abundant in unsettled regions. This is the species which plays a part in the famous triple alliance of prairie-dog, owl and rattlesnake, which, although popularly supposed to be a most amicable arrangement, is at best a state of armed neutrality and frequently of open warfare. The owls and snakes seek the burrows of the marmot as safe retreats and nesting sites, as well as for the purpose of feeding on the young marmots, while the latter frequently show their resentment of the intrusion in a variety of ways. A very distinct species is the horned rattlesnake (*C. cerastes*), in which the superciliary scales are produced into a pair of prominent horns surmounting the eyes. It is abundant in the desert region of the Southwest, especially about Death Valley, and is known in Arizona as the sidewinder from its peculiar habit of retreating sidewise from an intruder. Numerous other species inhabit these same hot dry regions.

Rattlesnakes possess a certain economic importance. As checks on the increase of the native mice and rats, they, in common with many other snakes, perform an important service. Their venomous qualities are such a menace to man and beast as to render their destruction both expedient and certain in all thickly settled districts. By the Indians and by the whites in certain parts of the South their flesh is relished; an oil or salve, supposed by the credulous to possess peculiar medicinal virtues, is claimed to be manufactured from their livers and other fatty parts; and the use of the skin for making purses, belts and other small articles is well known. Certain tribes of Indians employ these snakes in their ceremonials and others formerly poisoned the tips of their war-arrows with rattlesnake venom, while the rattles always figured among the charms of the medicine-man.

Rau, row, Charles, American archæologist: b. Vervien, Belgium, 1826; d. Philadelphia, Pa., 25 July 1887. He was educated at the University of Heidelberg and came to this country in 1848, where he engaged in teaching. From 1875 until his death he was curator in the National Museum at Washington, D. C., and devoted himself to the study of American archæology, on which he became a recognized authority. He wrote: 'Early Man in Europe' (1876); 'The Palenque Table in the United States National Museum' (1879); 'Articles on Anthropological Subjects, 1853-1877' (1882).

Rauch, rowh, Christian Daniel, German sculptor: b. Arolsen, Western Germany, 2 Jan. 1777; d. Dresden 3 Dec. 1857. In Arolsen he received his first instruction in art from the sculptor Valentin, under whom he executed ornamental work chiefly. Going to Cassel he became a pupil of Kuhl, the sculptor, and was appointed groom of the chamber in the king's household at Berlin. This gave him an opportunity of advancing in his art, and in 1802 he exhibited his 'Sleeping Endymion' and modeled a bust of Queen Louise (1804), which he subsequently executed in marble at Rome. In this city he found a patron in Humboldt, as well as in the first sculptors of the time, Canova and Thorwaldsen. Among his Roman work of early days must be mentioned the busts of the poet Werner, and the life-sized busts of Queen Louise, Count Weyerski, and the painter Raphael Mengs, executed under the commission of Ludwig of Bavaria. His colossal bronze statues of Blücher are 13 feet in height, and he also executed the greater part of the 12 statues in iron which compose the national monument at Kreuzberg, near Berlin. One of his finest works is the group 'Faith, Hope and Charity,' which he presented to his native town Arolsen, while his crowning work as a portrait and historic sculptor is his statue of Frederick the Great at Berlin (1851). He was one of the first, if not the very first, among German sculptors of his time, combining in his work the pure lines of transcendent dignity and grace with genuine portraiture of the individual. There is a poetic freedom in his conception of ideal subjects which does not yet overstep the limits of truth and fidelity to nature, and he may be safely styled the founder of the great Berlin school of sculpture. Consult: Eggers, 'Chr. D. Rauch' (1873); 'Rauch und Goethe, urkundliche Mittheilungen' (1880).

Raues Haus, row's hows (corrupted from "Ruges Haus"), an educational and benevolent institution at Horn, near Hamburg, founded in 1833 by J. H. Wichern, who long remained at its head. It is connected with the German Home Mission, and besides forming a refuge for neglected children, receives boarding pupils from the higher classes, and serves as a train-

ing school for those wishing to become teachers, superintendents, or assistants in hospitals, reformatories, houses of correction, and the like. It is supported by voluntary contributions, the profits arising from the productive enterprises carried on in connection with it, and the fees of the richer pupils. In 1903, about 90 poor children were receiving instruction within its walls. They live in "families" of from 12 to 15, each "family" being under the care of one of the adult members of the mission training school. The educational department is in the hands of assistants, who also take part in the instruction of the institution, in order to prepare themselves for the work of the Home Mission in other localities. This indeed has become one of the most important features of the work carried on by the Rauhes Haus, and its graduates are found in every field of charitable work in Germany. The whole staff of assistants, consisting of young men of 20 to 29 years of age, are formed into a kind of society (*Brüderschaft*). Since 1844 the institution has carried on a printing and book-binding business. Its organ is the 'Fliegende Blätter.'

Raum, rowm, Green Berry, American lawyer: b. Golconda, Ill., 3 Dec. 1820. He was admitted to the bar in 1853; removed to Kansas and served in the Union army in the Civil War, rising to the rank of brigadier-general of volunteers. He sat in Congress 1866-9; was commissioner of internal revenue 1876-83, and United States commissioner of pensions 1889-93. He has published: 'The Existing Conflict' (1884); 'History of Illinois Republicanism' (1900).

Raumer, row'mër, Friedrich Ludwig Georg von, German historian: b. Wörlitz, near Dessau, Anhalt, 14 May 1781; d. Berlin, Germany, 14 June 1873. He studied law at Halle and Göttingen, and entered the Prussian state service in 1801. In 1811 he accepted the chair of political economy at Breslau, and in 1819 was called to Berlin. He was for some time secretary of the Berlin Academy, and at different times between 1816-55 traveled extensively through Europe and the United States. In 1848 he was elected to the Parliament of Frankfurt, and was sent to Paris as ambassador. He was a member of the House of Lords of Prussia from 1851 until his death. He founded and edited in 1830-67 'Historisches Taschenbuch.' The first scientific historian to popularize history in German, Von Raumer wrote: 'Geschichte der Hohenstaufen und ihrer Zeit' (1823-5); 'Geschichte Europas seit dem Ende des 15. Jahrhunderts' (1832-50); 'Die Vereinigten Staaten von Nordamerika' (1845); 'Handbuch zur Geschichte der Litteratur' (1864-6).

Raumer, Karl Georg von, German geologist and educator, brother of the preceding: b. Wörlitz, Germany, 9 April 1783; d. Erlangen, Germany, 2 June 1865. He was educated in Göttingen, Halle, and Freiberg, and in 1811 became professor of mineralogy at Breslau, was called to Halle in 1819, and in 1827 settled permanently as professor of natural history at Erlangen. He published: 'Geognostische Fragmente' (1811); 'Lehrbuch der allgemeinen Geographie' (1832); 'Geschichte der Pädagogik' (1843-51); etc. Consult his autobiography (1866).

Raumer, Rudolph von, German philologist, son of Karl Georg von Raumer: b. Breslau, Ger-

many, 14 April 1815; d. Erlangen, Germany, August 1876. He was privat-docent at Erlangen in 1840-6; professor there in 1846-76, and published: 'Untersuchungen über die Urverwandtschaft der semitischen und indo-europäischen Sprachen' (1868 et seq.).

Raupach, row'pāh, **Ernst Benjamin Salomo**, German dramatic poet: b. Straupitz, near Liegnitz, 21 May 1784; d. Berlin 18 March 1852. He studied at Halle, afterward went as a tutor to Russia, and in 1816 obtained a chair in the philosophical faculty of the University of Saint Petersburg; but quitted the country in 1822, and after various changes finally settled, in 1824, in Berlin, where he employed himself chiefly in writing for the stage. His dramatic works have been collected and published in two divisions, the one containing his comic pieces, under the name of 'Dramatische Werke komischer Gattung' (1828-35); and the other, 'Dramatische Werke ernster Gattung' (1830-43). In his earlier works he was an imitator of Schiller, and some of the tragedies belonging to this period, such as 'Die Erdennacht,' show much real power. His popular success was considerable; but his dramas became more and more trivial in content. They display, however, considerable knowledge of stage effect, great creative power, and a wealth of verbal wit. A life of the dramatist was published by Pauline Raupach (1853).

Raupp, rowp, **Karl**, German painter: b. Darmstadt 1837. He began as a landscape painter, and between 1856 and 1858 studied genre under J. Becker at Frankfurt, and under Karl Piloty at Munich Academy from 1860 to 1865. Subsequently he opened a studio, taking private pupils in painting, and in 1868 his reputation as a teacher gained for him the position of professor in the art school at Nuremberg, which he held up to 1879, when he was appointed professor in the Academy at Munich. Among his works may be mentioned: 'A Boating Party on the Chiem See'; 'Home Before a Storm'; 'A Calm'; 'Ave Maria'; 'Sport and Work'; 'Starting Home from the Monastery School.'

Ravaiillac, François, räñ-swä rä-vä-yāk, French assassin: b. Touves, near Angoulême, 1578; d. Paris 27 May 1610. He was successively valet to an attorney, in which situation he learned to read and write; attorney's clerk, and schoolmaster. He could never succeed in any undertaking, however, and was thrown into Angoulême prison for debt, where he remained for a considerable time. At last he was released, and turned out into the world a beggar. He entered the order of the Feuillants, but was expelled shortly afterward as a visionary. His naturally gloomy disposition degenerated into fanaticism when he began to meddle in the religious controversies that distracted France. He came to consider King Henry IV. as the arch enemy of the Church, to destroy whom would be a meritorious work. On 14 May 1610, while the king's carriage was standing in the street, Ravaiillac approached and stabbed him. He was condemned to be torn to pieces by four horses, and this he underwent, previously declaring that he had no accomplices to his crime.

Ravana, rä'vā-nā, in Hindu mythology the Rakshasa, who, at the time of Rama, ruled over Lanka or Ceylon, and, having carried off Sita, the wife of Rama, to his palace, was ultimately

conquered and slain by the latter. He is described as a giant with 10 faces, who in consequence of austerities and devotion, had obtained from Siva a promise which bestowed on him immunity from the power of demons and gods. Vishnu became incarnate as Rama, and hence killed the demon giant, whose kingdom had been invaded by men with the assistance of monkeys, against whom Ravana, in scorn, had omitted to make any stipulations in his compact with Siva.

Raven, a typical species (*Corvus corax*) of the crow family (*Corvidæ*), of which, as indeed of all passerine birds, it is the largest representative. The size is quite variable, but is generally about two feet in length and four feet in expanse. Plumage, bill, and feet are all black, the former with rich purple and violet lustres, but duller in the young and females, which are likewise smaller. The raven inhabits Europe, a large part of Asia, and North America from the Arctic Ocean to Guatemala. In North America two sub-specific forms are found, *C. corax sinuatus* being the western, and *C. corax principalis* the larger northern and eastern race. The former is generally abundant in the Rocky Mountain region; the latter has been largely exterminated in the eastern United States, but is still found in many inaccessible waste and mountain districts and reaches a very large size in Labrador and northward. Northwardly the raven is migratory, but may withstand the cold of the severest winters, as it often does in Canada and about the Great Lakes.

It is most abundant in rocky districts, near the banks of lakes and rivers, and is generally seen alone or in pairs, but sometimes in small flocks after the breeding season; the flight is rapid, elevated, and protracted, often sailing for hours at a time at a great height; on the ground the gait is grave and dignified, with frequent opening of the wings. It is truly omnivorous, but by preference carnivorous, eating small animals of all kinds, eggs, and young birds, carrion, dead fish, mollusks, crustaceans, insects, nuts, and berries. The European raven is reputed to destroy young rabbits and even lambs. It disgorges indigestible substances, as bones, hair, and feathers, like birds of prey. It is very wary and cunning, and is rarely caught in traps or shot by the hunter, but it often falls a victim to the poisoned baits set by the trappers for the fur-bearing animals. It breeds, according to latitude, between January and June, making a rude nest on inaccessible cliffs or tall trees, repairing the same for years in succession; the eggs are four to eight, two inches long, light greenish blue with numerous light purple and yellowish brown blotches, especially at the larger end; incubation lasts about three weeks, and the young remain in the nest several weeks before they are able to fly, fed at first on the half digested food disgorged by the parents; only one brood is raised in a year, and this is bravely and successfully defended against the largest birds of prey. The raven is easily domesticated by kindness, and becomes much attached to its master, following him like a dog. Like others of the family it can be taught to imitate the human voice and to pronounce a few words with great distinctness; but the natural note is a deep, hoarse croak. The white-necked raven (*C. cryptoleucus*) of Mexico and the south-

western United States has the concealed bases of the neck feathers pure white. Several other raven-like species inhabit Africa. The large size, black color, mournful croak, charnel-house habits, together with the boldness, sagacity and wariness of the raven have combined to make it an object of superstitious fear and hate. As a bird of ill omen it was watched by the ancient augurs with close attention; it holds a prominent place in mythology and folklore, and receives frequent notice in literature.

Ravenel, Harriott Horry, American biographer: b. Charleston, S. C., 12 Aug. 1832. She was married in 1851 to St. Julien Ravenel M.D. She is a prominent member of the Society of Colonial Dames of America. She has published 'Ashurst' (1870); 'Life of Eliza Pinckney' (1896); 'Life and Times of William Lowndes of South Carolina' (1901).

Ravenel, Henry William, American botanist: b. Berkeley, S. C., 19 May 1814; d. Aiken, S. C., 17 July 1887. He was graduated from South Carolina College in 1832, made a life study of the fungi and cryptogams and became one of the best botanical authorities in the United States. He made a critical study of the phenogams of South Carolina, was botanist of the government commission to Texas in 1869, and was agricultural editor of the 'Weekly News and Courier.' The genus *Ravenelia* of the *Uredineae* is named in his honor. He wrote: 'Fungi Caroliniani Exsiccati' (1853-60); and with M. C. Cooke 'Fungi Americani Exsiccati' (1878-82).

Ravenna, ra-vě'n'a (It. *rā-vě'n'ā*), Italy, (1) capital of the province of the same name, 45 miles east of Bologna. Though standing in a low marshy plain it was once a flourishing city, and the seat of the exarchate of Ravenna of the Western Roman Empire, close to the Adriatic Sea, but now five miles distant. Laces, wines, and agricultural implements form the chief articles of trade. The salient points of interest are found in its ancient churches, museums, tombs, and historical landmarks, among which may be mentioned the palace and tomb of Theodoric, the temple containing Dante's tomb, and Lord Byron's house. Pop. (1901) 63,839. (2) The province has an area of 715 square miles; pop. (1901) 235,485.

Ravenna, ra-vě'n'a, Ohio, village, county-seat of Portage County; on the Baltimore & Ohio, the Erie, and the Pennsylvania R.R.'s; about 28 miles southeast of Cleveland. It is in an agricultural region, and has extensive industrial interests. The chief manufacturing establishments are foundries, machine shops, furniture factories, brick and tile works, electrical supply works, flour and lumber mills, iron and boiler works and cigar factories. It has a large trade in farm, clay, and iron products, and in livestock. In the vicinity are a number of small and beautiful lakes, which have been made popular outing places. Pop. (1890) 3,417; (1900) 4,003.

Ravenna Grass. See GRASSES IN THE UNITED STATES.

Ravenscroft, ră-věnz-křóft, Edward, English dramatist, who flourished between 1671 and 1700. He was exceedingly popular in his day, though his work was never original, consisting of translations from older plays, and at times he

even borrowed from his own previous works. His first play was 'Mamamouchi' (1671), taken from Molière's 'The Gentleman Citizen.' His plays include: 'The Wrangling Lovers' (1676), after Corneille; 'Scaramouch, a Philosopher' (1677); 'Dame Dobson' (1683); 'The Canterbury Guests' (1695); 'The Italian Husband' (1698); etc.

Ravenscroft, Thomas, English composer: b. near London 1592; d. London 1635. He was educated for his profession in St. Paul's choir, and at 15 received the degree of Bachelor of Music from Cambridge. In 1611 he published a collection of 23 part-songs, under the title 'Melismata,' which are of remarkable beauty. In 1614 appeared his 'Brief Discourses,' another collection of 20 part-songs to which he has prefixed an essay on the ancient musical modes. In 1621 he published his 'Whole Book of Psalms,' containing a chant for each psalm, many new, and all harmonized in four parts by Tallis, John Milton (the poet's father), Ravenscroft himself, and other musicians.

Ravenshoe, ră-věnz-hō, a novel by Henry Kingsley, published in 1862. The House of Ravenshoe, in Stonington, Ireland, is the scene of this novel; and the principal actors are the members of the noble family of Ravenshoe. The plot is remarkable for its complexity, and the book contains many bits of piquant humor.

Ravenslein, ră-věn-stin, Ernst George, Anglo-German geographer and statistician: b. Frankfort-on-the-Main 30 Dec. 1834. He was educated privately and in 1852 removed to London. In 1855-75 he was engaged in the topographical (now intelligence) department of the war office, was a member of the council of the Royal Statistical Society in 1877-92 and of the Royal Geological Society in 1894-6. He founded the German Gymnastic Society in 1861 and served as its president for 10 years and in 1882-3 he was professor of geography at Bedford College. He has published: 'The Russians on the Amur' (1861); 'Geographie und Statistik des Britischen Reiches' (1863); 'Map, Equatorial Africa' (1884); 'The Strange Adventures of Andrew Battell' (1901); etc.

Ravesteijn, ră-vě-stin, Jan van, Dutch painter: b. The Hague about 1572; d. there 21 June 1657. He was elected into the old Painters' Guild of Saint Luke at The Hague in 1598; the new guild was organized in 1655, and a Jan van Ravesteijn is enrolled among its members, but this may have been his son who bore the same name. He probably began his artistic studies under Frans Hals. His special department was portrait, in which he took rank among the first painters of Holland. Two large pictures of his with grouped portraits are to be seen in the Hall of the Company of Archers at The Hague; and in that city and at Antwerp are several portraits of individuals. His portrait picture of his own family is at Brunswick. His faces are life-like, his handling vigorous, and his coloring transparent, although somewhat too red to be quite natural.

Ravignan, ră-věn-yăn, Gustave Xavier Lacroix de, French Jesuit pulpit orator: b. Bayonne 1 Dec. 1795; d. Paris 26 Feb. 1858. He had already enlisted in the Bourbon cause in 1815, and, after juristic studies, been made auditor of the Paris supreme court (1817) and sub-

RAVEN TRIBE.

1. Jackdaw. 2. Magpie. 3. Raven. 4. Rook. 5. Gray Crow.

stitute attorney-general (1821), when in 1822 he entered the Jesuit novitiate at Montrouge. In July 1828 he was ordained priest, and subsequently was professor of theology at St. Acheul (1828-30) and at Brieg (Canton Wallis), Switzerland. He returned in 1835 to France, where he was for five years head of the Jesuit establishment at Bordeaux. In 1837 he took the place of Lacordaire (q.v.) at Notre Dame, and continued the "conferences" there until 1846. He spoke with much simplicity, but with intense conviction. Crowds flocked to hear him, the cathedral being, it is said, often filled hours before the sermon began. He has been considered one of the greatest preachers of his time. Among his writings were: 'De l'Existence et de l'Institut des Jésuites' (1844; 7th ed. 1855); and 'Clément XIII. et Clément XIV.' (1854). Consult the sketch by Ponlevoy (13th French ed. 1890; Eng. trans. 1873).

Ravine-deer, the name among East Indian sportsmen of the common gazelle of India (*Gazella bennetti*), which is numerous in open rocky places and on the plains from central India to Persia. See GAZELLE.

Ravogli, Augustus, American surgeon: b. Rome, Italy, 7 Feb. 1851. He was graduated from the University of Rome in 1873, studied medicine at Vienna, Prague, and Berlin, served as surgeon in the Italian army with the rank of major and came to the United States in 1880. He settled in Cincinnati, Ohio, in 1881, and shortly after became professor of dermatology and syphilography at the University of Cincinnati. He has published numerous scientific articles and 'The Hygiene of the Skin' (1888).

Rawal Pindi, râ'ûl pîn'dê, India, in the Punjab, (1) the administrative capital of the division and district of its own name between the Indus and Jhilm, on the railway from Lahore to Peshawar. It is modern in appearance, well-built, and an important grain market. There are an arsenal, a fort, a fine public park, several European churches and the headquarters of the Punjab Northern State R.R. Transit trade is carried on with Cashmere and Afghanistan. The Sikhs surrendered here, and in 1885 a great durbar or review was held. Pop. (1901) 87,688. (2) The Rawal Pindi division comprises four districts with a total area of 15,435 square miles. The district contains many towns connected with the campaign of Alexander the Great. Pop. 3,560,699.

Rawdon, Francis. See HASTINGS, FRANCIS RAWDON.

Rawhide, a form of leather in which the curing process stops short of destroying the life of the material. The result is a material remarkable for toughness, durability, tensile strength, and pliancy. It is used for belting rope, hydraulic packing, laces of various kinds, pinion wheels, washers, harness, mauls and mallets, trunks, saddles, artificial limbs, whips, lariats, etc.

Rawle, râl, William, American lawyer: b. Philadelphia, Pa., 28 April 1759; d. there 12 April 1836. He studied law in New York and in London, was admitted to the Pennsylvania bar in 1783, in 1791 was appointed by Washington as district attorney of Pennsylvania, and in 1794 assisted in the prosecution of the offenders in the Whiskey Rebellion. He acted

as counsel for the United States Bank for many years, was chancellor of the Associated Members of the Bar of Philadelphia, and of the Law Association of that city, and was a trustee of the University of Pennsylvania from 1796 until his death. He assisted in the revision of the civil code of Pennsylvania in 1830, was one of the founders of the Historical Society of Pennsylvania in 1824, serving as its first president, and was also president of the Abolition Society. He published: 'A View of the Constitution of the United States' (1825); 'Discourse on the Nature and Study of the Law' (1832); etc. Consult Wharton, 'Memoir of William Rawle' (1840).

Rawle, William Henry, American lawyer: b. Philadelphia 31 Aug. 1823; d. 19 April 1889. He was graduated at the University of Pennsylvania in 1841 and three years later was admitted to the bar, where he rapidly attained prominence. He enlisted in the Union army during the Civil War (1861) and re-enlisted in 1863, then serving as quartermaster. He was vice-provost of the Law Academy (1865-73) and vice-chancellor of the Law Association from 1880 to the time of his death. He published: 'Law of Covenants for Title' (1852); 'Equity in Pennsylvania' (1868); 'The Lease of the Educated Unemployed' (1885).

Rawlins, râ'linz, John Aaron, American military officer: b. East Galena, Ill., 13 Feb. 1831; d. Washington, D. C., 6 Sept. 1869. He took up the study of law and in 1854 began practice in his native town. In 1861, soon after the storming of Fort Sumter, he made a brilliant war speech at a meeting presided over by Ulysses S. Grant, who was so greatly impressed that he requested Rawlins to act as his assistant adjutant-general. He then entered the army, and throughout the war was Grant's closest friend and adviser. He took an active part in the campaigns of 1862-3, and was appointed brevet major-general 13 March 1865. He was a man of marked ability as a soldier, although he never had military training. General Sherman said that Rawlins "was an intense thinker and a man of vehement expression; a soldier by force of circumstances rather than of education or practice, yet of infinite use to his chief throughout the war and up to the time of his death." He was secretary of war during Grant's first administration.

Rawlins, Joseph Lafayette, American legislator: b. Salt Lake County, Utah, 28 March 1858. He received a classical education at the University of Indiana, but was not graduated, and was a professor at the University of Deseret in Salt Lake City 1873-5. He was admitted to the bar in 1875 and practised until 1892, when he was a successful candidate for Congress. Defeated for a second term in 1895 he was elected to the United States Senate in 1897, where in 1902 he was a member of the Committees on Foreign Relations, Immigration, Geological Survey, Indian Affairs, Pacific Railroads, Public Buildings and Grounds, and the Philippines.

Rawlins, Wyo., city, county-seat of Carbon County; on the Union Pacific Railroad; about 135 miles west by north of Laramie. It is the commercial centre of an extensive stock raising and mineral region. Its manufac-

tures are chiefly for local use; but the railroad shops give employment to a number of persons. It ships annually a large amount of minerals, sheep, wool, and live cattle. The State Penitentiary is at Rawlins. Pop. (1890) 2,235; (1900) 2,317.

Rawlinson, râ'lin-sôn, George, English Orientalist: b. Chadlington, Oxfordshire, 23 Nov. 1815; d. London 6 Oct. 1902. Educated at Oxford, he took orders and was made a fellow and tutor of Exeter College in 1840. In 1845 he became sub-rector, delivered the Bampton lectures in 1859, and in 1861 was made Camden professor of ancient history. He received from Mr. Gladstone a canonry of Canterbury Cathedral in 1872, and in 1888 accepted the living of All Hallows, Lombard Street, London. An indistinct utterance interfered with his public speaking and his pulpit was mainly filled by proxy. His learning was large and various and his services to Biblical scholarship of the highest importance. With his brother, Sir Henry Rawlinson (q.v.), and Sir George Wilkinson he published an annotated edition of Herodotus (1858-60). Among his other works are: 'The Historical Evidences of the Truth of Scripture Records' (1860); 'The Five Great Monarchies of the Ancient World' (1862-7); 'Historical Illustrations of the Old Testament' (1871); 'The Sixth Great Oriental Monarchy, or the Geography, History, and Antiquities of Parthia' (1873); 'The Seventh Great Monarchy' (Persian Empire) (1876); 'The Origin of Nations' (1877); 'Saint Paul in Damascus and Arabia' (1877); 'History of Ancient Egypt' (1881); 'Religions of the Ancient World' (1882); 'The Antiquity of Man Historically Considered' (1882); 'The Early Prevalence of Monotheistic Beliefs' (1883); 'Egypt and Babylon from Scripture and Profane Sources' (1884); 'Religious Teachings of the Sublime and Beautiful in Nature' (1884); 'Ancient History' (1887); 'Ancient Egypt' (1887); 'Moses: His Life and Times' (1887); 'A History of Phœnicia' (1889); 'Isaac and Jacob: Their Lives and Times' (1890); 'Parthia' (1893); and others in the department of Biblical commentary.

Rawlinson, Sir Henry Creswicke, English diplomatist and Orientalist: b. Chadlington, Oxfordshire, 4 Nov. 1810; d. London 5 March 1895. He went to Bombay in 1827 as a military cadet in the service of the East India Company, at once applied himself assiduously to the study of the Oriental languages, and was soon in request as an interpreter. After five years' service with the First Bombay Grenadiers, he was employed in military work in Persia (1833-9). His stay in Persia had made him acquainted with the cuneiform inscriptions at Behistun, and on being appointed in 1844 consul at Bagdad he set himself to copy and decipher the chief inscription. The result was his great paper on 'The Persian Cuneiform Inscription at Behistun,' printed in the 'Journal of the Royal Asiatic Society' in 1846. Though not without important predecessors in the same field, Rawlinson is justly regarded as the chief founder of the study of Persian cuneiform, and the first successful decipherer of cuneiform writings. Having shown great zeal and ability in the discharge of political duties, he was raised in 1851 to the rank of consul-general. Resigning in 1855, he returned to England, and in 1856 was created

K.C.B., promoted lieutenant-colonel, and appointed a crown director of the East India Company. In 1858 he was elected to the House of Commons for Reigate as a conservative, and again sat there in 1865-8 as member for Frome. In 1859-60 he was minister-plenipotentiary at Teheran, in 1889 became a G.C.B., and two years later was created a baronet. Rawlinson received many honors both at home and from foreign countries. He was president of the Royal Asiatic Society in 1878-81 and of the Royal Geographical Society in 1871-2 and 1874-5. His chief published works are: 'Cuneiform Inscriptions of Western Asia' (1861-80; 2d ed. of Vol. I., 1891), with E. Norris, G. Smith, and T. G. Pinches; 'England and Russia in the East' (1875), a strongly anti-Russian pamphlet; notes in the translation of 'Herodotus' by his brother, George Rawlinson (q.v.), and many papers in the journals of the Royal Asiatic and Royal Geographical Societies. See the 'Life' by his brother (1898), with an introduction by Earl Roberts.

Rawnsley, rânz'li, Hardwick Drummond, English Anglican clergyman and poet: b. Henley-on-Thames 28 Sept. 1850. He was educated at Oxford, took orders in 1875, was vicar of Wray, Windermere, 1878-83, and has been vicar of Crosthwaite, Keswick, from the last named date. Among his many published works are: 'Sonnets Round the Coast'; 'Sonnets at the English Lakes'; 'Literary Associations of the English Lakes'; 'Village Sermons'; 'Sonnets in Switzerland and Italy' (1899); 'Memories of the Tennysons' (1900); 'Ruskin and the English Lakes' (1901); 'A Rambler's Note Book at the Lakes' (1902).

Rawson, râ'sôn, Albert Leighton, American author and artist: b. Chester, Vt., 15 Oct. 1829; d. New York November 1902. He studied law, theology, and art and traveled extensively in the Orient, later exploring the Indian mounds in the Mississippi Valley, and traveling in Central America and in the Hudson Bay territories. He founded the Theosophical Society in the United States, was adopted into the tribe of the Adwan Bedouins of Moab and initiated by the Druses in Mount Lebanon. His books, illustrated by his own maps and drawings, include: 'Bible Dictionaries' (1870-5); 'Antiquities of the Orient' (1870); 'Vocabulary of the Bedawin Languages of Syria and Egypt' (1874); 'Chorography of Palestine' (1880); 'The Unseen World' (1888); 'History of Mysticism'; etc.

Rawson, Edward Kirk, American educator: b. Albany, N. Y., 21 Feb. 1846. He was graduated from Yale in 1868, from Andover Theological Seminary in 1872, and was ordained in the Congregationalist ministry. In 1871-90 he was chaplain in the United States navy, serving at the Naval Academy from 1886, and in 1888-90 professor of ethics and English there. In 1897-1902 he was superintendent of naval war records and in 1902 he resumed his chair at the Naval Academy. He has published 'Twenty Famous Naval Battles: Salamis to Santiago' (1899).

Ray, Anna Chapin, American author of juvenile fiction: b. Westfield, Mass., 3 Jan. 1865. She was graduated at Smith College 1883; and in 1888 received the degree of A.M. She has published 'Half a Dozen Boys' (1890); 'Half a

Dozen Girls' (1891); 'Dick' (1896); 'Each Life Unfulfilled' (1899); 'Bumper and Baby John' (1903); 'By the Good Sainte Anne' (1905).

Ray, George W., American lawyer and politician: b. Otselic, Chenango County, N. Y., 3 Feb. 1844. He was educated at Norwich Academy; served in the Civil War as private and brigade clerk; then studied law, was admitted to the bar in 1867, and established a successful practice. In 1882 he was elected to Congress as a Republican, and served till 1885, and again from 1891 to 1903. He opposed the free silver bill of 1892, was chairman of the committee on invalid pensions and of the committee on judiciary. In 1902 he was made United States district judge for northern New York.

Ray, Isaac, American physician: b. Beverly, Mass., 16 Jan. 1807; d. Philadelphia, Pa., 31 March 1881. He was graduated from Bowdoin in 1827, practised medicine, and in 1841-5 was superintendent of the state insane asylum at Augusta, Maine. In 1845-66 he had charge of the Butler Hospital for the Insane at Providence, R. I., and then removed to Philadelphia, where he engaged in medical practice. He published: 'Conversations on Animal Anatomy' (1829); 'Medical Jurisprudence of Insanity' (1838); 'Education in Relation to the Health of the Brain' (1851); 'Mental Hygiene' (1863); 'Contributions to Mental Pathology' (1873); etc.

Ray, John (at an earlier period spelled by him WRAY), English naturalist: b. Black Notley, near Braintree, Essex, 29 Nov. 1627; d. there 17 Jan. 1705. He was educated at Trinity College, Cambridge, was made Greek lecturer in 1651, mathematical lecturer in 1653; humanity reader in 1655, and junior dean in 1658. He made long botanical and zoological tours in England, Scotland, and Wales; and in 1663-6 traveled about Europe with Francis Willoughby in an attempt to accomplish a systematic description of the entire organic world. It is thought that much of the credit bestowed on Ray as the founder of English natural history should properly attach to Willoughby. Ray was elected F.R.S. in 1667. Among his works are 'Catalogus Plantarum Angliæ' (1670), the basis of all subsequent English floræ; 'Methodus Plantarum Nova' (1682), giving a new system of classification; 'Historia Plantarum' (1686-1704). In 1844 the Ray society was founded at London for the publication of scientific works of established merit. Consult the 'Memorials' by Lankester (1844).

Ray, a group of elasmobranchs forming the suborder *Batoidei*. The skates and the rays are nearly allied to each other, and are recognized by their broad flattened bodies, which are generally of a rhomboidal shape, and consist in greater part of the enormously developed pectoral or breast fins, which are supported upon a modified portion of the anterior skeleton. On the upper surface of the disk-like body the eyes are borne, together with spiracles or apertures, by which water may be admitted to the gill-sacs. The mouth, nostrils, and gill-openings (five on each side) are in the lower surface of the body. The mouth is generally furnished with broad flat teeth of rhomboidal shape, and is of small size. The tail is elongated and slender, and is generally armed with sharp spinous processes. (See STING-RAY.) Two or more

dorsal fins may exist, whilst the caudal or tail fin is heterocercal. These fishes produce eggs, which, like those of sharks, are enclosed in cartilaginous capsules, known as "mermaids' purses," etc. Occasionally the rays may attain very large dimensions, and weights. They are bottom-fishes, and feed upon other small fishes, crustaceans and mollusks. They swim chiefly by peculiar undulating motions of the edges of the pectoral fins. In the true rays (*Rajidae*) the snout is more or less pointed and prolonged, and two dorsal fins exist near the end of the tail. The most common members of this group are the sting-rays (q.v.). The European sharp-nosed ray (*R. oxyrhynchus*) is a favorite French food-fish; the homelyn ray (*R. maculata*), also, is frequently sold in the London markets. The American species are called skates (q.v.). The eagle rays (*Myliobatidae*) possess projecting heads, with the pectoral fins extended laterally in a great degree so as to imitate wings. The teeth are hexagonal, flat, and pavement-like. The slender tail possesses one dorsal fin, and is armed with a notched spine. These include the California "batfish" (*Myliobatis californicus*), and a famous whip-tailed species of the Mediterranean (*M. aquila*). Allied to these are the huge blanket-rays (*Mantidae*), so much dreaded by swimmers and divers in all warm seas. Specimens weighing more than 1,000 pounds have been taken in the Mediterranean. (See DEVIL-FISH.) Other families are the sawfishes (*Pristidae*), the guitar-fishes (*Rhinobatidae*) and the electric rays or torpedoes (*Narcobatidae*), elsewhere described. See FISHES; ICHTHYOLOGY.

Rayahs, rā'yāz, the Christian peasantry, laborers, and small farmers, who lived under Turkish rule, or rather misrule, in the Balkan peninsula. The word means "cattle," and as cattle these people were treated by their Turkish masters in Bosnia, Servia, Bulgaria, and the neighboring states.

Rayleigh, rā'li, **John William Strutt**, BARON, English physicist: b. 12 Nov. 1842. He was educated at Cambridge and became a fellow of Trinity College in 1866. From 1879 till 1884 he was professor of experimental physics at Cambridge, and since 1887 has occupied the chair of natural philosophy in the Royal Institution. He was secretary to the Royal Society from 1887 till 1896, and since the latter year has been scientific adviser to Trinity House. In addition to many contributions to the proceedings of scientific societies, Lord Rayleigh has written the article 'Optics' in the 'Encyclopædia Britannica' (9th edition) and a valuable work on 'The Theory of Sound' (1877-8; new ed. 1894-6). He was associated with Prof. William Ramsay in the latter's discovery in atmospheric nitrogen of a new gas, called by them argon, and forming approximately 1 per cent of the atmosphere.

Raymond VI., rā'mônd, count of Toulouse: b. 1156; d. 1222. He succeeded to the territory in 1194. He protected the Albigenses, against whom Pope Innocent III. sent an army in 1208 to avenge the assassination of his legate. Raymond's territories were ravaged, he himself excommunicated and his lands given over to Simon de Montfort. After the death of de Montfort at the siege of Toulouse in 1218 Raymond recovered his territories. But again

espousing the cause of the Albigenses he was once more excommunicated.

Raymond VII., son of Raymond VI., and last count of Toulouse: b. 1197; d. 1242. He engaged with his father for the recovery of Toulouse from Simon de Montfort, and finally forced the latter's son Amalric, to a complete surrender. Forced to make peace with the Pope and the king of France in 1229, he ceded Narbonne and other estates to Louis IX. He made Alphonse, Count of Poitiers, his heir.

Raymond, Andrew Van Vranken, American college president: b. Visscher's Ferry, N. Y., 8 Aug. 1854. He was graduated at Union College 1875, and at the New Brunswick Theological Seminary 1878. He was pastor of the First Reformed Church, Paterson, N. J., 1878-81; Trinity Reformed Church, Plainfield, N. J., 1881-7, and of the Fourth Presbyterian Church, Albany, N. Y., 1887-94. He has been president of Union College since 1894.

Raymond, Bradford Paul, American Methodist clergyman: b. Stamford, Conn., 22 April 1846. He was graduated from the Theological School of Boston University, and ordained to the Methodist Episcopal ministry in 1874. He held successive pastorates in New Bedford, Mass., Providence, R. I., and in Nashua, N. H., and was president of Lawrence University from 1883-9. From 1889 until his resignation in 1907 he was president of Wesleyan University, Middletown, Conn. He has published 'Christianity and the Christ.'

Raymond, Evelyn Hunt, American writer of juvenile fiction: b. Watertown, N. Y., 6 Nov. 1843. In 1869 she was married to J. B. Raymond and at present (1904) resides in Baltimore. Among her many popular books may be cited: 'Little Red Schoolhouse' (1897); 'A Daughter of the West' (1899); 'Reels and Spindles' (1900); 'The Sun Maid' (1900); 'A Daughter of the Forest' (1902).

Raymond, George Lansing, American educator: b. Chicago, Ill., 3 Sept. 1839. He was graduated from Williams College in 1862 and from Princeton Theological Seminary in 1865. Entering the Presbyterian ministry he was pastor at Darby, Pa., 1869-73; professor of oratory at Williams 1874-80; was professor of oratory and æsthetic criticism at Princeton 1880-93 and of æsthetics at Princeton from 1893. Among his many published works in verse and prose are: 'Life in Song' (1886); 'Poetry as a Representative Art' (1886); 'Ballads of the Revolution' (1887); 'The Representative Significance of Form' (1900); 'The Aztec God and Other Dramas' (1902).

Raymond, Henry Jarvis, American journalist: b. Lima, N. Y., 24 Jan. 1820; d. New York 18 June 1869. He was graduated from the University of Vermont in 1840, went to New York, studied law, and contributed to 'The New Yorker,' a literary weekly published by Horace Greeley. Upon the establishment of the New York *Tribune* in 1841 he became assistant editor. While editorially connected with the 'Courier and Enquirer' (1843-51) he engaged with Greeley in a spirited controversy on the subject of Fourierism, which had at that time taken a strong hold upon the American people resulting in the establishment of communities more or less resembling Brook Farm.

He was elected to the State Assembly in 1849 and 1850, the latter year becoming speaker. In 1851 he established the New York *Times*, the first number being issued on 18 September. In 1854 he was elected lieutenant-governor of the State. He was one of the prominent organizers of the Republican party, and drew up the "Address to the People," promulgated by its first national convention held in Pittsburg February 1856. His choice for President in 1860 was William H. Seward, and he used his influence to place him in the cabinet after Lincoln's election. After the disaster at Bull Run he proposed a provisional government, feeling that Lincoln's policy was too hesitating. He was again member of the Assembly in 1861, where he was chosen speaker; and in 1864 was elected to Congress, giving his support to President Johnson's policy. He was the author of the "Philadelphia Address" to the people of the United States, promulgated by the National Union Convention, which he helped to organize in 1866. He was an effective public speaker, and exerted a marked influence on the elevation of the tone of journalism. He wrote 'Political Lessons of the Revolution' (1854); 'Letters to Mr. Yancy' (1860); 'History of the Administration of President Lincoln' (1864); 'Life and Services of Abraham Lincoln' (1865). Consult Maverick, 'Henry J. Raymond and the New York Press for Thirty Years' (1870).

Raymond, John Howard, American educator: b. New York 7 March 1814; d. Poughkeepsie 14 Aug. 1878. He took his degree at Union College in 1832, entered the Baptist ministry, and in 1839 became professor of rhetoric and English literature at Madison University, and in 1850 removed to the newly established Rochester University as professor of belles-lettres. As an organizer of educational institutions he showed remarkable aptitude, performing that service for the Collegiate and Polytechnic Institute in Brooklyn in 1856 and for Vassar College in 1865. He filled the post of president and professor of mental and moral science at Vassar until his death. Consult his 'Life and Letters' (1880).

Raymond, John T., American actor: b. Buffalo, N. Y., 5 April 1836; d. Evansville, Ind., 10 April 1887. His original name was John O'Brien. His first appearance was at Rochester in June 1853, as Lopez in 'The Honeymoon.' In 1861 he made a great hit as Asa Trenchard in 'Our American Cousin,' and in 1867 went to England and appeared in this character in the company of E. A. Sothern, who was the famous Lord Dundreary. In 1874 he achieved his greatest success as Colonel Mulberry Sellers in a dramatization of Mark Twain's 'Gilded Age.' He was widely popular and depicted certain types of broad, humorous character with great success.

Raymond, Rossiter Worthington, American mining engineer: b. Cincinnati, O., 27 April 1840. He was graduated from the Brooklyn Polytechnic Institute in 1858 and spent three years in study at Freiburg, Munich, and Heidelberg. Returning from Europe he entered the Union army and served from 1862 to 1864 as additional aide-de-camp with the rank of captain. From 1864 to 1868 he was consulting engineer in New York, at the end of which time he was appointed United States commissioner of mining

RAYMOND — RAYNER

statistics and held this post until 1876. From 1870 to 1882 he was lecturer on economic geology at Lafayette College. In 1875 he became New York state commissioner of electric subways for the city of Brooklyn. One of the original members of the American Institute of Mining Engineers, he became its vice-president in 1871, was its president 1872-4, and secretary 1881-8. He is a member of scientific and technical societies in Europe and America, including the Society of Civil Engineers of France. In 1903 he became lecturer on mining law in Columbia University. He has published: 'Reports on the Mineral Resources West of the Rocky Mountains' (1869-76); 'The United States Mining Industry'; 'Mines, Mills, and Furnaces'; 'Silver and Gold'; 'Brave Hearts,' a novel (1873); 'The Man in the Moon and Other People' (1874); 'The Book of Job' (1878); 'Camp and Cabin' (1880); 'A Glossary of Mining and Metallurgical Terms' (1881); 'Memorial of Alexander L. Holly' (1883); 'Life of Peter Cooper' (1901).

Raymond, Walter, English novelist: b. Yeovil, Somerset, 13 March 1852. He was educated at private schools, and was partner in a glove manufactory, but in 1895 gave up business for literature. Among his works, several of which appeared under the pseudonym "Tom Cobbleigh" are: 'Misterton's Mistake' (1890); 'Gentleman Upcott's Daughter' (1894); 'Love and Quiet Life' (1894); 'Tryphena in Love' (1895); 'Two Men o' Mendip' (1898); 'The Idler Out of Doors' (1901).

Raymond, William Galt, American civil engineer: b. Princeton, Ia., 2 March 1859. He was graduated at Washington University as a civil engineer in 1884; was instructor of civil engineering at the California State University 1884-90; was professor of geodesy, road engineering, and topographical drawing at the Rensselaer Polytechnic Institute 1892-1904, and since 1904 professor of civil engineering and director of the School of Applied Sciences at Iowa State University. He has published 'Plane Surveying' (1896).

Raymond, Battle of. After the battle of Port Gibson (q.v.), 1 May 1863, the Confederates fell back beyond the Bayou Pierre and destroyed the bridges. Gen. Grant followed on the 2d, occupied Port Gibson, and the same evening the Confederates continued their retreat across Big Black River, at Hankinson's Ferry, leaving a force behind to prevent the crossing, which was attacked on the morning of the 3d by Crocker's division of McPherson's corps. The Confederates stoutly contested the ground, retiring very slowly, until late in the day, when Logan's division came upon their flank, when they hastily crossed the river. McPherson's corps was moved forward to Hankinson's Ferry and McClernand's to Willow Springs, where they remained until the 7th, when, Sherman's corps having crossed the Mississippi, the advance was resumed, the main body of the army moving along the line of the Big Black toward Edwards' Station, midway between Vicksburg and Jackson, while McPherson, on the right, was directed upon Jackson, the capital of the State, 45 miles east of Vicksburg, and the geographical and railway centre of the State. On the night of the 11th

McPherson bivouacked five miles northeast of Utica, on the road to Raymond, and early in the morning pushed rapidly for Raymond, 18 miles from Jackson, hoping to capture some commissary stores, but before 9 A.M. Logan's division, in the advance, encountered a strong body of the enemy, upon which the division was deployed and continued its advance for two hours, when, coming to a small stream crossing the road about two miles from Raymond, Gen. Gregg's brigade of about 3,000 men, with two batteries, was seen beyond the stream, disposed to enfilade the road and bridge over the stream. Logan threw out skirmishers and advanced, bringing on a severe engagement, which continued more than two hours, when the leading brigade of Crocker's division came up to his support, upon which Gregg, leaving two disabled guns, abandoned the field and retreated toward Jackson, being joined on the way by Walker's brigade, and when overtaken by night, bivouacking five miles from the field. The Union loss was 66 killed, 339 wounded, and 37 missing. Gregg reported a loss of 73 killed, 229 wounded, and 204 missing. Consult: 'Official Records,' Vol. XXIV.; Grant, 'Personal Memoirs,' Vol. II.

E. A. CARMAN.

Raynaud's (rā-nōz') Disease, a vasomotor affection, occurring mostly in children and young adults, and characterized by coldness and whiteness of the toes, the tips of the fingers, the end of the nose and sometimes of the lobes of the ears. It may exist with other functional nervous disorders, such as hysteria and neuralgia, and occurs especially in persons of neurotic heredity or temperament. It was first studied by Raynaud in 1862. He believed that the local manifestations are due to constrictor spasm, probably originating in the gray centres of the spinal cord. No central lesions have been found. After exposure to cold, the toes, fingers, nose, etc., become cold, numb, and white (local syncope), and pricking draws no blood. When warmth and color return, there is frequently pain, also congestion, swelling and a purple color (local asphyxia). Either of these stages may be recovered from, or the second stage may end in gangrene of the parts (Raynaud's gangrene, local or symmetrical gangrene). Recurrences of the disease are common. The prognosis is not good, especially in debilitated children. For treatment avoid cold, use warm baths, electricity, and massage. Ichthyol ointment sometimes alleviates the pain. Other remedies should be advised by the physician.

Rayner, rā'nēr, Emma, American novelist: b. Cambridge, England. She was graduated from Cambridge University, came to this country and was employed on the staff of the 'Youth's Companion' (1896-1902). She has published: 'Free to Serve' (1897); 'In Castle and Colony' (1899); 'Visiting the Sin' (1900); 'Doris Kingsley: Child and Colonist' (1901); 'Handicapped Among the Free' (1903).

Rayner, Isidor, American lawyer and politician: b. Baltimore, Md., 11 April 1850. He received his education at the University of Virginia, and entering on the practice of law, soon became one of the leaders of the Baltimore bar. In 1878 he was elected to the State legislature, serving later for four years in the State senate. In 1887 he entered Congress as a

member of the House of Representatives, where he participated in important legislation, and in February 1904 was elected to the United States Senate.

Raynouard, François Juste Marie, fränswä zhüst mä-rë rä-noo-är, French poet and philologist: b. Brignoles, department of Var, 8 Sept. 1761; d. Passy 17 Oct. 1860. He studied for the bar at Aix and practised law at Draguignan with great success. Elected a deputy to the Legislative Assembly in 1791, he attached himself to the Girondins, and on the proscription of that party was thrown into prison. The fall of Robespierre set him at liberty, whereupon he resumed his profession of advocate in his native province and acquired a fortune. Having previously made two unsuccessful attempts to live by his pen, he once more settled in Paris, and wrote 'Socrate dans le Temple d'Aglaure' (1802), a poem which obtained a prize from the Institut. This was followed by two tragedies, 'Eléonore de Bavière' and 'Les Templiers,' the latter performed at the Théâtre Français in 1805 by order of Napoleon. In 1806 he was elected a member of the Corps Législatif. In 1817 he was nominated perpetual secretary of the Academy, a post he resigned in 1826, when the ministry presented to the chambers a bill which had for its object the limiting of the liberty of the press. Of most value to the world is the work in the field of Romance philology, his writings including: 'Grammaire comparée des Langues de l'Europe Latine dans leurs Rapports avec la Langue des Troubadours' (1821); 'Choix des Poésies originales des Troubadours' (1816-21); 'Lexique Roman, ou Dictionnaire de la Langue des Troubadours comparée aux autres Langues de l'Europe Latine' (1836-44); 'Observations Philologiques sur le Roman de Rou, et sur quelques Règles de la Langue des Trouvères au XIIe Siècle' (1829).

Razin, rä'zën, Stenko, Russian bandit: b. —; d. Moscow 1671. He was the leader of Cossacks who plundered caravans and fisheries along the Volga. Being captured he was pardoned by Alexis, but rebelled again, and gathered about himself the dissatisfied elements, captured cities and ruled along the Volga as far as Nijni-Novgorod. He was finally taken and executed at Moscow. Thereupon he became the hero of epic song of the 17th century and was regarded as the champion of the people against the nobles. Magic powers were attributed to him.

Razor, the well-known keen-edged instrument for shaving off the beard or hair. Razors seem to have been in use at a very early period of the world's history. They were used by the ancient Egyptians. The Levitical code expressly forbade the shaving of the beard, and many Jews in some countries remove all superfluous hair with the scissors until this day. It is believed by many authorities that the primitive shaving-instruments were made of sharpened flints; the savages of Polynesia still use two pieces of flint of the same size, or pieces of shells or sharks' teeth ground to a fine edge, for this purpose. Among civilized nations the blade is metal, usually steel, the finest cast steel being preferred. The handles are made of a great variety of materials, as silver, ivory, tortoise-shell, bone, horn, etc. The Chinese and

Japanese razors are very rarely furnished with handles.

Razor-bill, or **Tinker**, a species of auk (*Alca torda*) intermediate in structure between the guillemots and the great auk; but characterized by its compressed, elevated, hooked, and furrowed bill, its peculiar stiff wedge-shaped tail and ample wings. It is about 18 inches long, generally black above and white below; but in the breeding plumage the head and neck become lustrous black all around, with a very characteristic fine white line running from the eye to the base of the bill. This bird is abundant in the North Atlantic, frequenting rocky islands and coasts to breed with puffins and guillemots, but at other seasons keeping farther out at sea, and in winter migrating as far south as the Mediterranean and the coast of New Jersey or even North Carolina. On the American side it breeds in the Bay of Fundy and in great colonies in the Gulf of St. Lawrence, about Labrador, etc. A single much blotched and streaked whitish egg, about three inches long, is deposited on a ledge or in a fissure of some precipitous rocky cliff. They feed upon floating refuse or fish, worms, etc., for which they dive or which they pursue in the water, using both wings and feet in swimming. When molested they sometimes fight viciously, at the same time uttering harsh cries. The large eggs are much gathered for food.

Razor-clam, or **Razor-fish**, a bivalve mollusk of the family *Solenida*, known on all sandy shores. The shell is long and narrow, like a razor-handle, and gapes at both ends, the siphons are short, the foot is large and powerful. The shell is handsomely ornamented and in some tropical species is of great beauty. These mollusks always live buried in the sand in an upright position, leaving only an opening shaped like a keyhole, which corresponds with the two siphon tubes. They are generally found at a depth of one or two feet, and when they make their burrows, as they are often in the habit of doing, among the rocks, not even an iron hook can draw them from their retreat, but they may sometimes be beguiled by pouring salt water on the spot, deceiving them into the impression that the tide has risen and they may begin to feed. They are edible, but rather tough. A familiar and typical species on the eastern coast of the United States is *Ensis americana*. Consult Kingsley, 'Standard Natural History,' Vol. I. (1885).

Razorback, one of the large whales of the genus *Balaenoptera*, called also finbacks and rorquals. (See FINBACK; WHALE.) Also a name for the thin and agile semi-wild hogs which range the woods in the less settled parts of the southern United States.

Re, rä, the sun god, first and most important of Egyptian divinities. Re is supposed to be the son of Neith (q.v.), the goddess of the upper air, and to have had for his wife Mout, the mother of nature. He had for children Athor, the light; Mu, the sunlight; and Mat, spiritual light, and was widely worshipped by the ancient Egyptians, and in course of time every local divinity became identified with Re; thus, Ammon became Ammon-Re; Sobk changed to Sobk-Re. The attempt to unify the personages of mythology under Re and thus erect a

monotheism is credited to Amenophis IV. of the 18th dynasty.

Ré, rā, or Rhé, Île de, France, a small, low-lying island three miles distant from the coast of the department of Charente-Inférieure, opposite the city of La Rochelle, from which it is separated by the Pertuis Breton. It is about 18 miles long and three broad and measures 28 square miles. The inhabitants are chiefly engaged in the preparation of salt, producing 32,000 tons annually. The west coast is rocky; on the east side there are some good harbors. Oyster farming has become an important branch of industry yielding 35,000,000 annually. Wine is made and exported. The chief town, St. Martin, was fortified by Vauban. Pop. of island about 15,000.

Reaction, in chemistry, a general term for any chemical change that is brought about by the mutual interaction of two or more substances. Reactions between two primitive substances may be conveniently divided into three classes, as follows: (1) Those in which the two substances combine additively, so as to form a single third substance by their union. (2) Those in which one of the primitive substances is broken up, the other primitive substance combining additively with one or all of its parts, so as to produce two or more new substances. (3) Those in which there is a double decomposition of the two primitive substances, the several parts of the first combining with those of the second so as to produce two or more new substances. The first of these is illustrated by the action of oxygen gas upon metallic sodium, the combination taking place additively according to the equation $2\text{Na} + \text{O} = \text{Na}_2\text{O}$. The second is illustrated by the action of chlorine gas upon an excess of methane (CH_4); methyl chloride and hydrochloric acid being formed (upon exposure to diffuse daylight) in accordance with the equation $\text{CH}_4 + 2\text{Cl} = \text{CH}_3\text{Cl} + \text{HCl}$. The third general type of reaction between two primitive substances (that, namely, in which there is a double decomposition) may be illustrated by the action of hydrochloric acid upon caustic potash, KOH, as indicated by the equation $\text{KOH} + \text{HCl} = \text{H}_2\text{O} + \text{KCl}$, the products of the reaction being water and chloride of potassium.

To describe chemical reactions in detail would be to discuss the entire subject of chemistry. Reference must therefore be made to the many articles in this encyclopædia in which different types of reactions are described. See, for example, AROMATIC COMPOUNDS; BENZENE; CHEMISTRY; EQUILIBRIUM, CHEMICAL; FATTY COMPOUNDS; SOLUTIONS; etc.

Read, rēd, George, American patriot and jurist, one of the signers of the Declaration of Independence; b. Cecil County, Md., 18 Sept. 1733; d. New Castle, Del., 21 Sept. 1798. He was educated at Chester, Pa., studied law, and was admitted to the bar in Philadelphia, soon afterward settling in New Castle, Del., where he practised his profession. He served as attorney-general for the crown for the counties of Delaware, Kent, and Sussex from 1763 to 1764, when he was elected a member of the first Continental Congress. Early an opponent of independence, at last he saw no alternative, and signed the petition to George III. and the Declaration itself. He was chairman (1775-7)

of the first naval committee of the colonies, and is to be considered as one of the chief founders of the primitive American navy. The new constitution of Delaware (1776) was drafted by him, and he was president of the convention which adopted it. He was made vice-president and acting president (governor) of the State of Delaware, whose laws he codified. In 1782 he was appointed judge of the United States Court of Appeals for Admiralty Cases. He was a delegate to the Annapolis Convention (1786) and to the Constitutional Convention (1787), and was elected to the United States Senate in 1789 and in 1791. Resigning in 1793, he became chief justice of Delaware, and held that office during the rest of his life.

Read, John Elliot, American journalist: b. Farmer,' Philadelphia, for 12 years. He has educated in the public schools and has written much for agricultural, religious, and literary periodicals. He was associate editor of 'The Working Farmer' in New York 10 years, and was corresponding editor of 'The Practical Farmer,' Philadelphia, for 12 years. He has published: 'Farming for Profit' (1880); 'Life Triumphant: A Study of the Nature, Origin and Destiny of Man' (1900); and also wrote 'A Brief History of the Principal Earlier Arctic Explorations from the 9th Century to the Peary Expedition' as the concluding section of 'Nansen in the Frozen World' (1897).

Read, John Joseph, American naval officer: b. New Jersey. He was graduated from the United States Naval Academy in 1861, served under Farragut during the Civil War, and on the Atlantic blockades, and in 1866 was promoted lieutenant-commander. He has received steady advancement, was made rear-admiral in 1900 with command of the receiving-ship Richmond, and in 1901 was placed in command of the navy yard at Portsmouth, N. H.

Read, John Meredith, American jurist: b. Philadelphia, Pa., 21 July 1797; d. there 29 Nov. 1874. He was a son of George Read, signer of the Declaration of Independence, was graduated at the University of Pennsylvania in 1812, and admitted to the bar in 1818. In 1822-3 he occupied a seat in his State's legislature, and later as city solicitor drew up the first statement of the finances of Philadelphia. He was United States attorney for the eastern district of Pennsylvania in 1837-44, and served as solicitor general of the United States; attorney-general of Pennsylvania, and chief justice of that State from 1860 until his death. With the formation of the Republican party he became one of its members, and by it was elected judge of the supreme court of Pennsylvania in 1858. His name was proposed as candidate for the presidency of the United States in 1860 and several votes were actually cast for him in the Chicago convention, though he used his personal influence in favor of Abraham Lincoln. His 'Views on the Suspension of the Habeas Corpus' (1863) became the basis of the act of 3 March 1863, authorizing the President to suspend the habeas corpus act. His legal opinions extend through 41 volumes of reports, while of his published addresses the principal are: 'Plan for the Administration of the Girard Trust' (1833); 'The Law of Evidence' (1864); 'Jefferson Davis and his Complicity in the Assassination of Abraham Lincoln' (1866).

Read, John Meredith, American diplomatist: b. Philadelphia, Pa., 21 Feb. 1837; d. Paris 27 Dec. 1896. He was a son of Judge Meredith Read (q.v.), was graduated at Brown University, and at the Albany Law School in 1859. He pursued the study of international law in Europe, was admitted to the bar in Philadelphia, and settled at Albany. From 1860 to 1866 he was adjutant-general of the State of New York. In 1869 he was appointed United States consul for France and Algeria, and during the period of the Franco-Prussian war he acted as consul-general for the German government, for which he received the thanks of both the French and German governments, and personal recognition of his services from Prince Bismarck. From 1873 to 1879 he was United States minister to Greece, and during the latter part of his tenure of office personally paid the expenses of the legation, when the government refused the appropriation. His important services during his term were his securing the revocation by the Greek government of an order prohibiting the sale of the Bible in Greece; the release of the American ship *Armenia*, and the report of an open Russian port during the Turkish war, to which he urged the despatch of a grain fleet. After his relinquishment of diplomatic duties he continued to reside in Europe, engaged in archaeological, historical, and art studies. He was the author of a 'Historical Inquiry Concerning Henry Hudson' (1866).

Read, Nathan, American inventor: b. Warren, Worcester County, Mass., 2 July 1759; d. near Belfast, Maine, 20 Jan. 1849. He was graduated from Harvard in 1781; studied medicine; in 1796 established with others the Salem iron foundry, where chain cables and other iron work for ships were manufactured, and in 1798 patented a nail-making machine. In 1788 he became interested in steam navigation, and as his first task attempted the construction of a boiler that should be at once compact, light, and safe. He made, in 1788 or 1789, the first drawings of what he styled his "portable furnace boiler," which was devised for use on steam carriages and steamboats, and for which he obtained a patent 26 Aug. 1791. He had built a steamboat in 1789, and by a trial of this craft, which was fitted with paddle-wheels and a crank operated by hand, was satisfied that his method of applying steam to the propulsion of vessels would work suitably. There is no evidence, however, that he succeeded in even an experimental demonstration of his plans. His model steam carriage, exhibited by him while endeavoring to obtain aid in his schemes, was never developed. He did, however, invent the vertical multi-tubular firebox boiler, which has long been in use as a standard form. Among his other inventions were several forms of pumping engines, and a plan for utilizing the force of the tide by means of reservoirs alternately so filled and emptied as to produce a continuous stream of water. Much credit belongs to Read for his early and clear perception of the importance of steam navigation. From 1800 to 1803 he was a representative in Congress, and after his removal to Maine, was for many years chief justice in the court of Hancock County. Consult: Read, 'Nathan Read' (1870); Thurston, 'A History of the Growth of the Steam Engine' (1878).

Read, Opie Percival, American journalist: and novelist: b. Nashville, Tenn., 22 Dec. 1852. He was educated in Gallatin, Tenn.; entered journalism at Franklin, Ky., and later removed to Little Rock, Ark. He edited the *Arkansas 'Gazette'* in 1878-81; founded the *'Arkansaw Traveler'* in 1883, and edited it for 10 years. He has since lived in Chicago, where he has devoted himself to literary work. His publications include: 'Len Gansett' (1888); 'Up Terrapin River' (1889); 'A Kentucky Colonel' (1890); 'My Young Master' (1896); 'In the Alamo' (1900); 'Our Josephine' (1902); etc.

Read, Thomas Buchanan, American poet and painter: b. Chester County, Pa., 12 March 1822; d. New York 11 May 1872. His father was a farmer and he received but little schooling. He lived at various times during his youth and young manhood at Philadelphia, Cincinnati, New York, and Boston, occupied in ways that satisfied his tastes, such as portrait painting and writing verses, when he could; and in other ways that supplied his necessities, such as sign painting, cigar making, play acting, when he must. He published his first verses in the *Boston Courier* in 1843-4; later a Revolutionary tale 'Paul Redding' (1845) and 'Poems' (1846), before his removal to Philadelphia, where he edited 'The Female Poets of America' (1848), and brought out his 'Lays and Ballads' (1849). In 1850 he went to Europe and joined the circle of American artists living at Rome. Here he had the first opportunity for the serious study of painting, and for the rest of his life, save for occasional visits to America, he made his home at Rome. His better known paintings are 'The Water Sprite'; 'The Lost Pleiad'; 'The Star of Bethlehem'; 'Sheridan and His Horse.' He made portraits of Mrs. Browning, the ex-Queen of Naples, Henry W. Longfellow, and a group of Longfellow's children. His portrait of George Peabody is at the Institute in Baltimore. A sculptured bust of General Sheridan was executed late in life. It is as a poet, however, that he will be remembered, especially by his stirring 'Sheridan's Ride,' written for the elocutionist and actor, James E. Murdoch, and the exquisitely musical lyric 'Drifting.' His volumes of verse are 'The New Pastoral' (1855); 'Sylvia or the Last Shepherd' (1857); 'The Waggoner of the Alleghanies,' in which occurs the fine lyric 'The Maid who Binds Her Warrior's Sash' (1862). A complete edition of his poems was published in 1882.

Reade, rēd, Charles, English novelist and play-writer: b. Ipsden House, Oxfordshire, 8 June 1814; d. Shepherd's Bush, London, 11 April 1884. He was educated at Oxford and was called to the bar in 1843, but, finding literature more attractive than law, devoted himself to the former, and never practised. He became first known by his novel of 'Peg Woffington' (1852), which he afterward dramatized with Tom Taylor, under the title of 'Masks and Faces.' This was followed by 'Christie Johnstone' (1853), in which he showed considerable appreciation of certain characteristics of Scottish life. The appearance, in 1856, of 'Never Too Late to Mend,' one of his "novels with a purpose," in which he attacked the English prison system with, perhaps, greater zeal than unbiased judgment, secured for him a wide reputation. His next great work, the most scholarly and artistic

of his writings. 'The Cloister and the Hearth,' dealing with the lives of the parents of Erasmus, appeared in 1861, and is decidedly his masterpiece, though it has not attained the popularity, with the general reader, of some of his more melodramatic novels. Among the more important of his other works are: 'Love Me Little, Love Me Long' (1859); 'Hard Cash' (1863); 'Griffith Gaunt' (1866); 'Foul Play' (with Dion Boucicault, 1869); 'Put Yourself in His Place' (1870); 'A Terrible Temptation' (1871); 'The Wandering Heir' (1872); 'A Perilous Secret' (1884). He was also the author, either alone or in collaboration with others, of several dramas, including 'Gold'; 'Two Loves and a Life'; 'The King's Rivals'; and 'Drink,' the last adapted from Zola's 'L'Assommoir.' None of these won much success for Reade. His 'Courier of Lyons,' renamed 'The Lyons Mail,' has been made famous by Sir Henry Irving in the dual role of Lesurques and Dubosc. Reade was enthusiastic by nature, and continually filled with new enthusiasms toward any cause which roused his easily excited interest. The abuses in the convict prison system produced, as was said, one of his best-known novels; the system of private lunatic asylums furnished the motive for 'Hard Cash,' as the trades-union outrages at Sheffield did for 'Put Yourself in His Place,' while in 'Foul Play' he attacked the alleged practice of overloading and over-insuring ships. His writings show considerable skill in the delineation of character, much narrative, descriptive, and dramatic power, combined at times with coarseness and theatricality. He may, perhaps, be said to rank first in the second order of English novelists of the 19th century, and was as popular in this country as in his own. Consult: Swinburne's article in his 'Miscellanies' (1886); 'Charles Reade: A Memoir' (1887); Ireland, 'Extracts,' with an introduction (1891); and the 'Gentleman's Magazine' for 1882.

Reade, John, Canadian Anglican clergyman and journalist: b. Ballyshannon, Ireland, 13 Nov. 1837. He was educated at Queen's College, Belfast, and in 1856 went to Canada, where he founded the Montreal 'Literary Magazine,' and was also connected with the Montreal 'Gazette.' He engaged in teaching, practised law at intervals, and in 1864 took orders in the Church of England. In 1887 he was elected president of the Montreal Society for Historical Studies. He wrote: 'The Prophecy and Other Poems' (1870); 'Language and Conquest' (1883); 'The Making of Canada' (1885); 'Vita sine Liberis' (1886); 'Aboriginal American Poetry' (1887); etc.

Reade, William Winwood, English traveler and novelist, nephew of Charles Reade (q.v.): b. Ipsden, Oxfordshire, 30 Jan. 1838; d. Wimbledon, Surrey, 24 April 1875. He visited the western coast of Africa in 1862, and in 1868 started from Sierra Leone and reached the source of the Niger. He was special correspondent for the London *Times* in the Ashantee war, 1873-4. Of his literary work perhaps his most notable effort is 'The Martyrdom of Man' (1872), a history of human slavery. His other works include 'The Veil of Isis' (1861); 'Savage Africa' (1863); 'The African Sketch Book' (1873); 'Story of the Ashantee Campaign' (1875); 'The Outcast' (1875); etc.

Read'er, Francis Smith, American journalist: b. Coal Centre, Pa., 17 Nov. 1842. He was connected with the United States Civil Service for 10 years, and served with the Union army throughout the Civil War. Later he became editor of the Beaver Valley 'News.' He published 'Life of Moody and Sankey' (1890); 'History of the 5th West Virginia Cavalry' (1890); 'History of New Brighton, Pa.' (1899).

Reader. See ORDERS, HOLY.

Reading, rēd'ing, England, capital of the county of Berkshire, 28 miles southeast of Oxford. It has handsome municipal buildings; a public hall, and free library; a museum, and excellent schools. There are remains of the magnificent Benedictine Abbey founded by Henry I., in which he was buried. Henry VIII. converted the castle into a palace; later it was destroyed during the Cromwellian wars, and the gateway alone has been restored. Other churches are St. Mary's, rebuilt from a nunnery founded by Elfrida to expiate the murder of her stepson (Edward the Martyr); St. Lawrence (Norman), rebuilt in the 15th century; St. Giles' (mixed architecture), and Greyfriars Church. Reading was the headquarters of the Danes in 871; was a refuge for the students who defied the Parliament; for the law courts obliged to leave London to escape the terrible plague, and was the fighting ground of rival armies during the conflicts of the rebellion. Reading is the centre of a large agricultural district, has an active trade and various important industrial establishments. Pop. (1901) 72,214.

Reading, Mass., town in Middlesex County, on the Boston & Maine railroad, about 10 miles north of Boston. It was settled in 1638, and six years later was incorporated. It is a beautiful residential town, and has considerable manufacturing interests. The chief manufactured products are imitation leather, wire brushes, boots and shoes, rubber and rubber goods, games, church organs and organ pipes, toys, and furniture. The public library contains nearly 10,000 volumes. The government is administered by town meetings, which convene annually. Pop. (1890) 4,088; (1900) 4,969.

Reading, Pa., city, county-seat of Berks County; on the Schuylkill River and the Schuylkill Canal, and on the Pennsylvania, the Wilmington & Northern, and the Philadelphia & Reading R.R.'s; about 58 miles northwest of Philadelphia, and 55 miles east by north of Harrisburg. Its area is about six square miles. Reading was first settled by Germans, but later a number of English colonists located there, and named the place after Reading in England. In 1748 it was laid out, and in 1783 was incorporated as a borough. It was chartered as a city in 1847. It is in an agricultural region, in which there is great mineral wealth. It has extensive manufacturing and commercial interests. East of the city is Mount Penn, and south of it is Neversink Mountain. Inclined and electric railways extend to the summit of both mountains. Mount Penn is 1,140 feet above sea-level, and on its top is a stone tower 50 feet high. The chief industries are connected with iron and steel productions, but the coal mines and limestone quarries contribute to the industrial wealth of the city. The chief industrial establishments

are railroad shops, machine shops, foundries, potteries, paper and wood pulp mills, breweries, knitting mills, hosiery mills, hat factories, carriage works, cigar factories, and iron and steel works. The capital invested in manufacturing in 1900 (Federal census) was \$27,975,628, and the average annual output was valued at \$36,902,511. The iron and steel industries had the largest invested capital and about one fourth of the output. There were, in 1900, over 500 manufacturing establishments, representing about 100 different industries. The principal public buildings of Reading are the government building, the county court-house, city-hall, opera house, Masonic Temple, the churches and schools. The charitable institutions are Saint Catherine's Orphan Asylum (girls), city and county orphanages, House of the Good Shepherd, Saint Joseph's, the Reading, and the Homoeopathic hospitals. The educational institutions are the Schuylkill Seminary, the Inter-State Commercial College, Mount Saint Michael's Academy, Reading Classical School, Reading Academy and Business College, two high schools, a number of private schools, and two school libraries.

The city has an excellent park system covering in all nearly 200 acres. The government is vested in a mayor, who holds office three years, and a council. The members of the board of education are chosen by popular election. The annual municipal expenditures for maintenance and operation are about \$930,000; the chief items being, for schools, \$257,000; for the water department, \$234,500; for the police department, \$53,200; for municipal lighting, \$60,000; for streets, \$60,000, and for fire department, \$35,000. The waterworks cost the city originally \$1,937,762. They are owned and operated by the municipality. In 1867 and 1869 the city boundaries were enlarged. Pop. (1783), when it became a borough, 2,100; (1847), when chartered, 12,000; (1900), 78,961.

Readjusters, or **Refunders**, the name of a political party in Virginia, which passed several bills providing for the scaling and partial rejection of the public debt of the State. Virginia, at the close of the Civil War, was greatly impoverished, burdened with a large indebtedness, and shorn of part of its territory, which had been erected into the State of West Virginia. The reconstruction government added considerably to the debt, and a keen controversy arose over the question of meeting the obligations. An act passed in the legislative session of 1870-71 to refund the debt was repealed, but the repeal was declared unconstitutional by the courts. In 1878 the Legislature passed a measure known as the McCulloch bill, which provided for new bonds, to be exchanged at par for outstanding bonds, and to bear interest at 3 per cent for 10 years, 4 per cent for the following 20 years, and 5 per cent for 10 years, when the principal would fall due. This act did not satisfy those opposed to payment of the debt in full, who became known as "Readjusters," and included in their ranks both Democrats and Republicans. Under the leadership of H. H. Riddleberger they succeeded in getting control of the Legislature, and passed a bill scaling the debt from \$31,102,571 to \$19,665,196. This bill was vetoed by the Governor. In 1881 the Readjusters obtained complete control of the State, and laws were enacted in accordance with their policy, the same course being pursued in 1884,

1886, and 1887. The United States Supreme Court delivered nine opinions declaring the readjustment measures, so far as they prohibited the receipt of State bond coupons for taxes, as provided by the McCulloch law, to be in conflict with the provision of the Federal Constitution, upholding the obligation of contracts. The State could not be coerced into payment, and matters remained unsettled until a compromise was agreed upon between the State and holders of the bonds.

Reagan, re'gan, **John Henninger**, American politician: b. Sevier County, Tenn., 8 Oct. 1818; d. Palestine, Texas, 6 Mar. 1905. At 21 he settled in Texas, where he practised law and was a member of the Texas Legislature in 1847. In 1856 he was elected judge of the district court, but resigned the next year to go to Congress, of which he remained a member until 1861. During the Civil War he served as postmaster-general of the Confederate States, and acting secretary of the Confederate Treasury. He was a member of the Texas Constitutional Convention 1875, member of the Congress 1875-97, United States Senator 1887-91, and afterward chairman of the Texas State Railroad Commission. He introduced the "Reagan Inter-State Commerce Bill," on which the present interstate commerce legislation is based.

Real, re'al, a Spanish coin, the old unit of value in Spain. By the monetary law of June 1864, the silver real was made to weigh 1.208 grams, .81 fine, and equivalent to $4\frac{1}{2}$ cents. It has varied in value from $4\frac{1}{2}$ to 10 cents.

Real Presence, the doctrine of the actual presence of the body and blood of Christ in the Eucharist. See CONSUBSTANTIATION; EUCHARIST; MASS; TRANSUBSTANTIATION.

Real Variable, **Theory of Functions of the**; a mathematical science. A variable is a symbol (such as x or y or "time" or "temperature") which stands for any member of a class of things. A particular member of the class is called a "value" of the variable which is said to "take on" its values. One variable, y , is said to be a single-valued function of another variable, x , if to every value of x there corresponds one and only one value of y . This is the case, for example, if x stands for any number and $y = x^2$. It is customary to express such a relation between y and x by the equation $y = f(x)$; x is called the independent and y the dependent variable. If the restriction that only one value of y shall correspond to each value of x is removed, y is called a multiple-valued function of x . Unless otherwise provided, the word function in the following pages shall mean single-valued function.

While the notions of variable and function as thus defined apply to any class of objects whatever, they are usually thought of only in connection with classes of numbers. In fact the phrase Theory of Functions is at present understood by mathematicians to mean either the theory of functions of a complex variable ($q.v.$) or the theory of functions of a real variable. In a certain abstract sense, the theory of the complex variable might be supposed to include the theory of the real variable, since all values of the real variable x_1 are included as special values ($x_2 = 0$) of the complex variable $x_1 + x_2\sqrt{-1}$. As matter of fact, however, the theory of functions of a complex variable has yet concerned itself but little ex-

cept with analytic functions, *i.e.*, those functions which may be thought of as defined by a power-series together with its continuations. This theory therefore leaves untouched the widest class of functions of the real variable. On the other hand, since the theory of functions of a complex variable gives a broader and hence more unified theory of analytic functions than can be furnished by the real function theory, these functions are not ordinarily given special attention in the latter theory. For a discussion of algebraic functions the reader is referred to the article on Algebra; for transcendental functions, *i.e.*, functions which are not algebraic, see TRIGONOMETRY, HARMONIC ANALYSIS, DIFFERENTIAL EQUATIONS, SERIES etc.

The theory of functions of a real variable is a product of the critical tendency of mathematics in the latter half of the nineteenth century. It has yielded comparatively few new theorems about the functions hitherto studied in applied mathematics, and has therefore had less influence on these sciences than has the complex variable theory. Its main business has been the restatement in rigorous form and with proper limitation of generality, the brilliant though sometimes inexact theorems won by the earlier students of infinitesimal calculus. For example, the study of vibrating strings, membranes, etc., and of the conduction of heat led to the celebrated trigonometric series of J. B. J. Fourier (*q.v.*), which was at first incorrectly supposed to furnish a method of representing an arbitrary function. The reconsideration of this series and the attempt to determine exactly what functions are expandible by trigonometric series has led to many of the most abstruse theorems about point-sets. The theory of point-sets (Punktmengen, 'Assemblages of Points'; see article ASSEMBLAGES, GENERAL THEORY OF), it should be remarked in explanation of the proportionately large space allotted to it below, is the most characteristic feature of real function theory.

The Real Variable.—The real numbers are, first, the whole numbers positive and negative; second, the rational fractions of the form m/n where m and n are whole numbers, and, third, the irrational numbers such as $\sqrt{2}$ and π . On this subject, see the articles on Arithmetic and Algebra, and the Bibliography⁸ at the end of this sketch. (Reference numbers such as that on the word Bibliography correspond to the numbers attached to works in the Bibliography.)

The totality of real numbers is a field (Körper), *i.e.*, a set of elements upon which can be performed the operations of addition and multiplication, according to the well-known rules.⁸ We suppose also known the derived operations of subtraction, division, and raising to a power. A special symbol is used to distinguish the numerical from the algebraic value of a number: if x is positive, $|x|=x$, if x is negative, $-|x|=x$. The relation of greater and less is indicated by the symbols $<$, $>$; $a>b$ means a is greater than b , $a<b$ means a is less than b . Considerable attention has been given to the problem of stating explicitly the hypotheses of the real number system. We state here only that one the discussion of which has had the most far-reaching consequences.

Principle of Continuity.—If $[x]$ is any set of real numbers all less than a certain number, b , then there is a number, \bar{x} , such that every

number of $[x]$ is less than or equal to \bar{x} , and such that \bar{x} is the smallest number of which this is true. In other words, $x \leq \bar{x}$ for every x of $[x]$, and if $a < \bar{x}$, there is a number x' of $[x]$ such that $a < x'$.

Any number, such as b in the statement above, which is larger than every number of a set $[x]$ is called an upper bound of $[x]$; a number smaller than every number of a set $[x]$ is called a lower bound of $[x]$. In this language the principle of continuity says that every set having any upper bound has a least upper bound. It follows immediately that every set having a lower bound has a greatest lower bound. The greatest lower bound or least upper bound of a set may or may not belong to the set. Thus, zero is the greatest lower bound of the set of all positive numbers but does not belong to it; on the other hand, zero is the least upper bound and does belong to the set of all real numbers which are not positive.

A very large proportion of the advances in critical sharpness of the modern analysts over those of the seventeenth and eighteenth centuries is due to the recognition of places where the earlier analysts had unconsciously assumed, or had neglected to apply, the principle of continuity. The form in which this postulate is here stated is due to K. Weierstrass^{1, 2}. Other forms have been given by R. Dedekind³ and G. Cantor⁴. Indeed, the theory of continuity and irrational numbers is due about equally to these three great Germans.

Segment, Interval, Limit Point.—By the method of analytic geometry (*q.v.*) there is a correspondence between the totality of real numbers and the points of a line; likewise between the set of all pairs of numbers (x, y) and the points of a plane, the pair (x, y) corresponding to the point of which x and y are the coordinates. On account of this correspondence, it is customary to use geometrical language in the theory of real functions; thus, the word point is used interchangeably with the word number. A linear segment is the set of all numbers x , $a < x < b$, or the set of all points between a and b ; a planar segment is the interior of a parallelogram with sides parallel to the coordinate axes, or the set of all number-pairs (x, y) , $a < x < b$, $c < y < d$. The word interval is used for a segment plus its boundaries, *i.e.*, $<$ is replaced by \leq in the definition just given. A segment, linear or planar as the case may be, including a point, is called a neighborhood of the point.

Among the most important consequences of the principle of continuity is the following theorem which was first stated in a slightly different form by E. Borel¹¹ in 1895. Since its method is essentially involved in the proof of the theorem of uniform continuity (see below) given by E. Heine⁵ in 1871, it is usually called (after A. Schoenflies⁶) the Heine-Borel theorem:

Every set of segments $[\sigma]$ such that every point of an interval, i , is an interior point of at least one σ , has a finite subset $\sigma_1, \sigma_2, \dots, \sigma_n$, such that every point of i is an interior point of at least one σ_k ($k=1, 2, \dots, n$).⁹

We shall prove this theorem only for the linear case, the proof of the planar case being quite analogous. Let the end points of the interval i be a and b , $a < b$. Let $[b']$ be a set including every point, b' , of i such that the interval ab' is contained in a finite number of

segments of $[\sigma]$. There is at least one b' ; for one of the end points of any segment of $[\sigma]$ which includes a is evidently a point of $[b']$. By the principle of continuity, the set of all points, $[b']$, has a least upper bound B , $B \leq b$. We shall prove that B is a point of $[b']$ and that $b' = b$.

Let $a''b''$, $a'' < b''$, be a segment of $[\sigma]$ including B . Since B is the least upper bound of $[b']$ there is a point of $[b']$, b_1' , between a'' and B . But if $\sigma_1, \sigma_2, \dots, \sigma_e$ is the finite set of segments including all points of the interval ab_1' , this set together with $a''b''$ will include B , which proves that B is a point of $[b']$. Moreover, if $B < b$, the set $\sigma_1, \sigma_2, \dots, \sigma_e$ together with $a''b''$ would include every point of an interval ac , c being a point between B and b'' . c would therefore be a point of $[b']$ contrary to the hypothesis that B is an upper bound of $[b']$. Hence $B = b$ and the Heine-Borel theorem is proved.

A point a in every neighborhood of which there are points, distinct from a , of a set $[x]$ is a limit point of $[x]$; a either may or may not be a point of the set $[x]$. If $[x]$ is a linear set, a is either the greatest lower bound of the numbers of $[x]$ greater than it or the least upper bound of the numbers of $[x]$ smaller than it. A linear point-set without an upper bound is said to have the limit point $+\infty$ and one without a lower bound to have the limit point $-\infty$. The following theorem of Weierstrass is a simple corollary of the Heine-Borel theorem.

"Every infinite set of points lying on an interval has at least one limit point." If it had no limit point, then about every point of i there would be a segment including not more than one point of $[x]$. This set of segments, by the Heine-Borel theorem, would have a finite subset including all the points of i . But each interval of the subset not containing more than one point of $[x]$, $[x]$ could contain at most a finite number of points, contrary to hypothesis.

If $[x]$ is a linear point-set, and if we allow $+\infty$ and $-\infty$ to figure as limit points, the theorem may, of course, be modified to read: every infinite linear point-set has at least one limit point.

Theory of Linear Point-sets.—The set of limit points of a set $[x]$ is called the first derived set of $[x]$. The first derived set of the first derived set is the second derived set, etc. The theory of successive derived sets has been highly developed by the aid of the transfinite numbers of Cantor⁴ (see ASSEMBLAGES). A set which includes its first derived set is said to be *closed* (*abgeschlossene*). A set included in its derived set is *dense in itself* (*insichdicht*). A set which is both closed and dense in itself, is said to be *perfect*. An example of a set closed but not dense in itself is furnished by the number 0,

together with the numbers $\frac{1}{2^n}$ ($n=1, 2, 3, \dots$).

A set dense in itself but not closed is the set of all rational numbers. The set of all numbers is an example of a perfect set.

A set whose derived set is the set of all real numbers on a certain interval is *everywhere dense* (*überalldicht*) on this interval. Such a set has a point between every two points of the interval. A set which is everywhere-dense on no interval is nowhere dense. The first of the examples above is a nowhere-dense set, the second and third are everywhere-dense sets.

If $[x]$ is a closed set, nowhere dense on an interval ab , and c any point of ab not in $[x]$, then there is a segment, including c , whose end points belong to $[x]$, but which contains no point of $[x]$. Such a segment is called a point-free segment of $[x]$. Thus, for every closed set $[x]$ there exists one, and only one, set of point-free segments. No two of these segments overlap. Therefore they are an enumerable (or denumerable) set (see ASSEMBLAGES), namely, there can be only a

finite number of length $\geq \frac{b-a}{2}$, a finite number

of length $\geq \frac{b-a}{4}$, and in general only a finite

number of length $\geq \frac{b-a}{2^n}$. The set $[s]$ of end

points and limit points of end points of the point-free segments is evidently a closed set and is identical with $[x]$. Since the set of point-free segments is enumerable, its end points are enumerable and thus the nowhere-dense closed set is the derived set of an enumerable set of points. A consequence of this which we do not stop to prove here is that there is a one-to-one correspondence between the continuum and any perfect subset of itself; the argument depends on the theory of point-free segments and the fact that the continuum is the derived set of the enumerable set of all rational numbers.⁶

The notion, length of an interval, finds a generalization in the *content* of a point-set. $[x]$ being any set of points on an interval i , let $\sigma_1, \sigma_2, \dots, \sigma_n$ be any finite set of intervals of length l_1, l_2, \dots, l_n , including every point of $[x]$. Let $L = l_1 + l_2 + \dots + l_n$. There are, of course, an infinity of numbers, L . Their greatest lower bound is called the *content* of $[x]$ and written $c[x]$. If $[x]$ is a closed set and S is the sum of the finite or infinite series obtained by taking the lengths of the point-free segments in the order of their magnitude, we have $c[x] = l - S$, where l is the length of the interval i . Thus in the case of a closed set $[x]$ and its complementary set $[\bar{x}]$, which consists of all points of the interval not points of $[x]$, we have $c[x] + c[\bar{x}] = l$.⁶ This, however, is not true of sets in general. For example, the set of all rational numbers between 0 and 1 has the content unity and the set of all irrational numbers on the same interval has the same content. The notion of length is therefore extended by the definition of content, only to closed sets and not to sets in general. A much more far-reaching generalization of length has, however, been suggested by E. Borel¹¹ and carried out by H. Lebesgue¹² in connection with the theory of definite integrals (see below).

Functions Defined on an Interval.—On account of the generality of the definition, practically no theorems are known which apply to all functions on a given interval. One of the most general theorems known is obtained by introducing the restriction that on a certain interval, $f(x)$ shall have an upper bound. By this it is meant that there shall be a number, B , such that for every x on the given interval $f(x) \leq B$. From the principle of continuity it is clear that a function having an upper bound upon an interval, i , has a least upper bound B_0 , and by aid of the Heine-Borel theorem, it is easily proved that there is at least one point, x_1 , on the interval, such that for every interval of i

which includes x_1 , B_0 is the least upper bound of $f(x)$. This is a theorem of Weierstrass.¹

Another broad class of functions is that of the monotonic functions.¹ A function, $f(x)$, is monotonic increasing if whenever $x_1 < x_2$, $f(x_1) < f(x_2)$; it is monotonic decreasing if whenever $x_1 < x_2$, $f(x_1) > f(x_2)$. In the case of a monotonic function, $f(x)$, not only is there a single value of $y=f(x)$ for every value of x , but for every value of y taken on by $f(x)$ there is one and only one value of x . In this case it is the custom to write $x=f^{-1}(y)$ and to call $f^{-1}(y)$ the inverse function of $f(x)$. Thus every monotonic function, $f(x)$, has a single valued inverse which, however, is not necessarily defined for all values of y .

In antithesis to the monotonic functions stand oscillating functions, those such that on the interval under consideration there are three values of the independent variable, x_1, x_2, x_3 , $x_1 < x_2, x_2 < x_3$, such that $f(x_1) < f(x_2)$, $f(x_2) > f(x_3)$, or $f(x_1) > f(x_2)$, $f(x_2) < f(x_3)$. There exist functions which oscillate on every interval; indeed, a function may oscillate on every interval and still be continuous and have a continuous derivative.⁶ The definition of continuity is given below and of derivation in the article CALCULUS. In most investigations hitherto the functions considered have had only a finite number of oscillations; i.e., there would exist a finite set of points such that on the intervals between successive points the function would not oscillate. It is to be noted that a non-oscillating function is not necessarily monotonic; there may be intervals upon which it is a constant.

The word oscillation is also used to denote a measure of the total amount of variation of a function on a given interval, that is, the difference between the upper and lower bounds of $f(x)$. This is a satisfactory measure in case $f(x)$ is monotonic. In other cases, especially in case of functions with oscillation on every interval, this scheme is naturally extended as follows: Let $x_1, x_2, x_3, \dots, x_{n-1}$ be any finite set of points on the interval ab in the order $a < x_1 < x_2 < x_3 \dots < x_{n-1} < b$. Calling $a=x_0$ and

$b=x_n$, we have $\sum_{k=1}^n (f(x_k) - f(x_{k-1})) = f(b) - f(a)$.

But $\sum_{k=1}^n |f(x_k) - f(x_{k-1})| = R$ is, except for non-oscillating functions, different from $f(b) - f(a)$. For every finite set of points x_1, x_2, \dots, x_{n-1} , there is a value of R . The least upper bound, V , of the set of all possible numbers, R , is called the variation of $f(x)$ on the interval ab . A function for which V is finite is called a function of limited variation; such a function can always be expressed as the difference between two monotonic functions. Functions of limited variation were first defined and studied by C. Jordan in connection with the theory of lengths of curves.

Theory of Limits. — Turning from the description of a function by its properties on an interval to a consideration of its appearance in the immediate neighborhood of a point, we are led to consider the notions of limits and of continuity. If a is a limit point of a set of points $[x]$, then the variable x is said to approach a on the set $[x]$. In case all the values of x are $\geq a$, the approach is said to be from above, and in the opposite case, from below. Let $f(x)$ be a function which is defined and bounded on an in-

terval ab , $a < b$, and let x_1, x_2, \dots be any set of points of ab of which a is the only limit point. Such a set is, for example,

$$a + \frac{b-a}{2}, \quad a + \frac{b-a}{4}, \dots, a + \frac{b-a}{n}, \dots$$

The points whose coordinates are $(x_1, f(x_1))$, $(x_2, f(x_2))$, etc., in the graphical representation of $f(x)$ are a bounded set in the plane, and therefore have at least one limit point. The x coordinate of this point cannot be other than a , since every other x coordinate may be surrounded by a segment including at most one point of the set, x_1, x_2, \dots . Call the y coordinate of this point, y_0 . The value y_0 is such that for every pair of positive numbers, ϵ and δ , there is a value of $x > a$, such that $|x-a| < \delta$ and $|f(x) - y_0| < \epsilon$. A number, y_0 , satisfying this condition is called a value approached by $f(x)$ as x approaches a from above. If in every interval $a\bar{x}$ of ab , $f(x)$ is without an upper bound, $f(x)$ is said to approach the value $+\infty$ as x approaches a from above; if $f(x)$ is without a lower bound in every interval $a\bar{x}$, $f(x)$ approaches $-\infty$. Thus we have the highly important theorem that as x approaches any finite value from above (and by parity of reasoning, from below) $f(x)$ approaches at least one value, finite or infinite.

A finite value approached by $f(x)$ as x approaches $+\infty$ is a number, y_0 , such that for every pair of positive numbers, ϵ and δ , there is a value of x such that $x > \delta$ and $|f(x) - y_0| < \epsilon$. $f(x)$ approaches $+\infty$ as x approaches $+\infty$ if, for every ϵ and δ , there is a value of x such that $x > \delta$ and $f(x) > \epsilon$. The definition of approach to $-\infty$ is analogous. In the case where x approaches a finite value, x_0 , from above or below or from both sides, $f(x)$ approaches y_0 if for every pair of positive numbers, ϵ and δ , there is a value of x ($x \neq x_0$), such that $|x - x_0| < \delta$ and $|f(x) - f(x_0)| < \epsilon$. The theorem of the last paragraph now extends to all cases: if x approaches any value finite or infinite, $f(x)$ approaches at least one value, finite or infinite.

If $f(x)$ approaches only one value as x approaches a , the value approached is said to be the limit of $f(x)$ (or limiting value of $f(x)$) as x approaches a , and is indicated by the symbol L $f(x)$ or simply $Lf(x)$. If $L(f(x)) = f(a)$ the

function $f(x)$ is said to be continuous at the point $x=a$. A necessary and sufficient condition for the existence of the equality $Lf(x) = f(a)$ is the following: for every $\epsilon > 0$ there exists a $\delta_\epsilon > 0$, such that for every $x \pm a$ for which $|x-a| < \delta_\epsilon$, $|f(x) - f(a)| < \epsilon$. This condition, which is frequently taken as the definition of a limit,^{3,7} has to be appropriately modified in the cases where a and b are replaced by $+\infty$ or $-\infty$. The following is a necessary and sufficient condition that $Lf(x)$ shall exist and be finite:^{1,9} for every $\epsilon > 0$ there exists a $\delta_\epsilon > 0$, such that for x' and x'' distinct from a and such that $|x'-a| < \delta_\epsilon$ and $|x''-a| < \delta_\epsilon$, $|f(x') - f(x'')| < \epsilon$.

The proof of these necessary and sufficient conditions and also of the following theorems must be omitted for lack of space. If $f_1(x)$ and $f_2(x)$ approach definite limiting values as x approaches a , then $f_1(x) + f_2(x)$, $f_1(x) - f_2(x)$, and $f_1(x) \cdot f_2(x)$ approach $Lf_1(x) + Lf_2(x)$, $Lf_1(x) - Lf_2(x)$, and $Lf_1(x) \cdot Lf_2(x)$ respectively, as x approaches a ; if $Lf_1(x) \neq 0$, then $f_1(x)/f_2(x)$ approaches $Lf_1(x)/Lf_2(x)$. These propositions are evidently

to be thought of also as propositions about continuous functions. To them should be added the statement that if $f_1(x)$ is continuous at $x=a$ and $f_2(y)$ is continuous at $y=f_1(a)$, then $f_2(f_1(x))$ is continuous at $x=a$. Also, if $f(x)$ is continuous at a point $x=a$, and if $f(a)$ is positive, then there is a neighborhood of $x=a$ upon which the function is positive.¹

In the above propositions about limits it is not necessary that $f(x)$ be defined at every point of an interval. Everything we have said about $Lf(x)$ remains valid when x takes values on any set of which a is a limit point. Indeed, in one of the most important cases, that of the summation of series (*q.v.*) the independent variable takes on only integral values, and $a=+\infty$. For the following theorems, however, we assume that $f(x)$ is defined at every point of an interval.

Continuous Functions.— $f(x)$ is continuous on an interval ab if it is continuous at every point of the interval; in particular, it must be continuous at a and b . One of the most famous propositions of real function theory states the principle of uniform continuity:⁵ if ϵ is any positive number, there is $\delta_\epsilon > 0$, such that on every interval of ab of length less than δ_ϵ the oscillation of $f(x)$ is less than ϵ . Other propositions in this connection are that a continuous function has a finite maximum value $f(x_1)$ and a finite minimum value $f(x_2)$ and takes on all intermediate values.⁶ An important corollary of this is that every algebraic equation of odd degree with real coefficients has one real root. If a function is monotonic and continuous, it has a monotonic and continuous inverse.

If $f_1(x)$ and $f_2(x)$ are continuous on an interval ab and if $f_1(x) = f_2(x)$ on a set everywhere dense on ab , then $f_1(x) = f_2(x)$ at every point of the interval ab . The last theorem enables us to say that if a continuous function is known at every point of an everywhere dense subset of an interval, it is known on the whole interval. Since there are enumerable everywhere dense subsets, a continuous function is thus capable of determination by an enumerable set of conditions. This phenomenon is also manifested in the theorem that any continuous function may be expressed as a convergent series of polynomials. Generalizations of this theorem to discontinuous functions have been obtained by R. Baire,¹³ the next class of functions beyond the continuous being those discontinuous functions which are representable by series of continuous functions.

The class of continuous functions includes as a subclass the differentiable functions, *i.e.*, those continuous functions which possess at every point a derivative (see CALCULUS). The existence of a derivative, which amounts to the condition that the graph of $f(x)$ shall possess a tangent, puts a limitation on the manner in which a function may oscillate.⁷ The earlier students of calculus assumed that every continuous function may be differentiated, in fact, several proofs of this statement were offered. Weierstrass² was the first to give an example of a function which is everywhere continuous and such that for no interval is it differentiable at every point.

A subclass of the differentiable functions is constituted by those functions for which the second, third, and in general the n th derivatives exist. For such a function a formal expansion by means of Taylor's formula (cf. SERIES, CALCULUS) is always possible, but as has been

shown by A. Cauchy and A. Pringsheim,¹ this series need not always converge and, if convergent, need not represent the function. A function which may be represented by Taylor's series is called analytic. Necessary and sufficient conditions for the expansibility of functions by Taylor's series have been given by Pringsheim, but the full significance of the existence of all the derivatives of a continuous function is still to be determined.

Another outstanding problem in connection with continuous functions is that of the orders of infinities and infinitesimals. A function $f(x)$ becomes infinite or infinitesimal at a point if it approaches $+\infty$, $-\infty$, or 0. If $f(x)$ and $\phi(x)$ both become infinite (or infinitesimal) at the same point, a , we may have their quotient approaching (1) more than one limit, (2) a unique finite limit, not zero, (3) zero, (4) $+\infty$. For the first case no extensive theory has been developed. In the second case the functions are said to be of the same order; in the third case $f(x)$ has an infinity of lower order or is infinitesimal of higher order than $\phi(x)$; in the fourth case $f(x)$ has an infinity of higher order or is infinitesimal of lower order than $\phi(x)$. For analytic functions the notion of order is well established, for other functions not.

Discontinuous Functions.—A function may fail to be continuous at a point in several ways. In the first case, $Lf(x)$ may exist but be different from $f(a)$. In this case the discontinuity is called removable (*hebbare*), because by modifying the value of $f(a)$ to be the same as $Lf(x)$ a continuous function is obtained. If $Lf(x)$ fails to exist, $f(x)$ may still approach definite limits from above and from below. These limits are usually indicated by $f(a+0)$ and $f(a-0)$. $f(a)$ may coincide with either of them or differ from both. All these cases are referred to as discontinuities of the first kind.¹ If $f(a+0)$ or $f(a-0)$ fails to exist, that is, if $f(x)$ approaches more than one value as x approaches a from the right or from the left, $f(x)$ is said to have a discontinuity of the second kind at $x=a$. For this to occur, $f(x)$ must have an infinity of oscillations in every neighborhood of $x=a$. Such a function is $\sin\left(\frac{1}{x}\right)$ in the neighborhood of $x=0$.

It is easily provable that there is a finite or infinite greatest value approached by $f(x)$ on either side of $x=a$ and likewise a finite or infinite least value approached. These four numbers are generally denoted by $\bar{f}(a+0)$, $\bar{f}(a-0)$, $\underline{f}(a+0)$, $\underline{f}(a-0)$. The differences among these four numbers and $f(a)$ give a variety of ways of defining a measure of the amount of discontinuity at a point. For example, the lower bound of the oscillation of $f(x)$ on every interval which includes $x=a$ is the difference between the greatest and the least of these five numbers and is called the oscillation of $f(x)$ at $x=a$.

In classifying discontinuous functions according to the distribution of the points of discontinuity over an interval there are two cases of which other cases are compounds. On the one hand, are the totally discontinuous functions, *i.e.*, functions discontinuous at every point, such, for example, as the function which is $+1$ if x is a rational number and -1 if x is an irrational number. On the other hand, every interval may contain a point where $f(x)$ is con-

continuous; such a function is called point-wise discontinuous, though there is some divergence of usage in this particular.¹ A point-wise discontinuous function has the property that the points where the oscillation is greater than any fixed positive number, ϵ , constitute a nowhere-dense closed set. On considering an infinite

sequence, $\epsilon, \frac{\epsilon}{2}, \frac{\epsilon}{4}, \dots$ of such numbers, it is

evident that the set of points of discontinuity of a point-wise discontinuous function is an enumerable set of nowhere-dense closed sets.

The theory of discontinuous functions has received perhaps its main impetus from the study of definite integrals (see CALCULUS). It is easily seen by aid of the principle of uniform continuity that every continuous function is integrable and it is also evident that a totally discontinuous function is not integrable. Riemann proved that a necessary and sufficient condition for the integrability of a discontinuous function is that the set of points at which the oscillation of $f(x)$ is greater than any positive number shall be of content zero.² Thus an integrable function is continuous or so point-wise discontinuous that the set of points of discontinuity is an enumerable set of sets of content zero.

The content of a point-set is the definite integral of a function which is equal to unity for all points of the set and to zero for all other points. Corresponding to the Borel-Lebesgue generalization of content is a generalization of the definite integral, due to Lebesgue,¹² which extends the notion to a very broad class of functions. This generalization has been guided largely by the aim to state the definitions of differentiation and integration in such a way that they shall be inverse operations. According to the usual definitions (see CALCULUS) this is true for a limited class of functions, but there exist, on the one hand, functions whose integrals cannot be differentiated, and, on the other hand, functions whose derivatives cannot be integrated. The only effective generalization of the derivative that has been suggested in this connection is the substitution for the regular limit of $[f(x) - f(x_1)]/[x - x_1]$, one of the upper and lower bounds of the values approached by it as x approaches x_1 from above or below.

Attempts to generalize the limiting process in various directions are characteristic of the present tendencies in analysis. The principal results so far have been obtained in connection with infinite divergent series by Cesaro, Mittag-Leffler, Borel,¹³ and others. Another class of problems is the solution of functional equations. For example, it is known that among continuous functions, if $f(x+y) = f(x) + f(y)$, then $f(x) = ax + b$. But is this true if the restriction of continuity be removed?

Functions of More than One Variable.—The above account has dealt entirely with functions of one variable. A single-valued function of several variables, $f(x_1, x_2, \dots, x_n)$ is a variable y such that to every set of values (x_1, x_2, \dots, x_n) there corresponds one, and only one, value of y . The theory of such functions differs from that which we have been considering mainly in that the point-sets involved are no longer linear, but, rather, n dimensional. The approach to a point in a limiting process may now take place not only from two sides but by an infinity of paths. In grasping this situation, the principal idea so far advanced is that of uniform convergence

(cf. SERIES). But on this subject the reader is referred to the treatises cited below.

OSWALD VEBLEN,

Associate in Mathematics, University of Chicago.

Realf, rälf, Richard, Anglo-American poet: b. Framfield, Sussex, 14 June 1834; d. Oakland, Cal., 28 Oct. 1878. He published a volume of verse, 'Guesses at the Beautiful,' when 18; came to the United States in 1854, settling in Kansas, and, becoming a follower of John Brown, enlisted in the Union army in 1862, and wrote some of his best poetry in the field. Among his best-known poems are 'My Slain' and 'Indirection.' A collection of his poems was edited by R. J. Hinton (1899).

Realgar, a gorgeous, aurora-red mineral found massive and in transparent or translucent, monoclinic crystals of short prismatic habit. Its lustre is resinous, hardness 1.5 to 2; streak orange-red. Analysis shows that it contains sulphur 29.9, arsenic 70.1, yielding the formula AsS or arsenic monosulphide, though it is usually regarded as arsenic disulphide, As₂S₂. Upon exposure to light it soon disintegrates, changing to a pulverulent, orange-yellow orpiment (As₂S₃) and white arsenolite (As₂O₃). Several localities in Hungary and neighboring countries are of commercial as well as mineralogical importance. It has recently been discovered in Macedonia, at Mercur in Utah, and massive, in enormous deposits, in the State of Washington. Its previous rarity precluded its use in the manufacture of art

senious oxide, for which purpose it is now extensively mined in Washington. Artificial realgar, known as "red orpiment" or "ruby sulphur," when mixed with nitre forms "white Indian fire."

Realism, (1) a term used in two fundamentally different senses in the history of philosophy. (a) During the period of Scholasticism (q.v.), realism denotes the doctrine that universals have in some sense an existence which is independent of the particular things that appear to the senses. This theory is derived from Plato's doctrine of ideas, and goes back ultimately to the Socratic view that only through the concept, or universal idea, is it possible to obtain real knowledge. Plato, developing this position, maintained that the universals, as ideas, exist apart from the world of sensible appearances, and form the true and abiding reality, while the latter is merely the world of imperfect copies, the transitory and inadequate representations of this true world of supersensible existence. In spite of the differences in name, then, and the necessary difference of interest in the problem due to the special intellectual outlook of the times, mediæval realism in its earlier and extreme form is identical in standpoint with Platonic Idealism. The later mediæval realists, under the criticism of nominalism (q.v.), modified the extreme view that universals exist apart from things, in the same direction in which Aristotle modified Plato's doctrine of the separate existence of ideas. That is, instead of defending the extreme proposition that universals exist prior to and independent of things (*universalia ante rem*), they maintained with Aristotle that it is the universal, the type or form, that constitutes the particular an individual thing, and that the two are therefore always found together (*universalia in rebus*). The whole problem of the relation of the universal and the particular, as it presented itself to the Scholastic mind, received its most adequate statement and solution at the hands of Thomas Aquinas. He pointed out that there is a sense in which all of the formulas that had been proposed by realists and nominalists alike are true and justifiable. We may say that the universal is prior to the thing and independent of it, inasmuch as we must suppose that the idea as a universal, existed in the mind of God before particular things were created; and in this sense we may therefore accept the statement *universalia ante rem*. But it is the presence of universals that gives to particulars their reality, and it is through their presence in things that they are known to us; therefore the formula *universalia in rebus* is justified. Furthermore, it is the particular, not the universal, that is first known to us. So that from the standpoint of our knowledge, we may admit the nominalistic proposition *universalia post rem*.

(b) In modern philosophy, realism has an entirely different meaning, and is directly opposed to idealism (q.v.). Realism in modern systems assumes many forms, just as idealism does, and the two views approximate to each other in so-called doctrines of ideal-realism. But yet the fundamental distinction between these two types of thought remains, and may be definitely stated as follows. Realism maintains that the universe is composed of a larger or smaller number of

"reals" that exist in and for themselves, independently of any relation to mind. Its main historical contention has been in opposition to any theory that would reduce the world to a system of ideas. Usually the argument of the realists has been directed against the type of idealism that attempts to interpret reality in terms of the consciousness of finite individuals. But it also maintains that real things possess a being outside and in a real sense independent of the absolute experience of God. We may grant, the realist would argue, that God knows all things, yet these things are not merely his ideas, but possess a reality and independence of their own. These real things are variously conceived in the different systems. In the Scottish Philosophy (founded by Thomas Reid 1710-96), we have the doctrine of "Natural Realism." That is, things are regarded as real just as they are given through immediate perception. In knowing, the mind deals directly with independent real things. This reality is guaranteed by "Common Sense," or the fundamental intuitions of mankind. By Kant, on the contrary, the world of perceptive experience is regarded as merely a phenomenon of consciousness. There remains for Kant, however, a world of things-in-themselves beyond experience which can never be known, but which we are necessarily obliged to think as the basis of the phenomenal world. As completely unknown and unknowable, this world of ultimate reality is incapable of any description or theoretical treatment whatever. Herbert Spencer, who speaks of his view as "Transfigured Realism," occupies fundamentally the same position as Kant. Herbert (1776-1841), while agreeing with Kant that the world of sense experience is phenomenal and exists only for a knowing consciousness, still holds that it is possible to define and determine by means of metaphysical investigation the nature of reality in itself. He therefore postulates the existence of a plurality of absolute "Reals" (*Reale*), each of which is simple and unchangeable, and between which relations obtain which give rise to the phenomenal order of experience. Leibnitz (1646-1715) in his doctrine of Monads, Fechner (1801-87), and Lotze (1817-81), regard the ultimate of nature of reality to be a system of psychical forms of existence or souls.

(2) In the Fine Arts and in Literature, Realism is opposed to Idealism. In general, it may be said that realism insists on correspondence with nature, on representing things as they are actually found in experience, while idealism tends toward an imaginative treatment which does not limit itself to reality as actually known. These two methods of treatment can never be absolutely exclusive of each other. In the work of any given individual one element or the other may be most prominent, but both must be present if the picture or statue or writing is to rank as an artistic production. Both in the choice of subject and in the details of his treatment the realistic artist idealizes: that is, he interprets the actual by isolating it from the context or environment in which it appears, and which serves to some extent to hide its true significance, and secondly, he also idealizes by representing in his treatment what is universal and essential, omitting certain things and selecting others with this end in view. On the other hand, the idealist who

"bodies forth the forms of things unseen," or sings of "a light that never was on sea or land," must nevertheless be "true to nature," in the sense that his imagination must work in accordance with the laws of reality. Otherwise the result is something grotesque and fantastic. We do, however, speak of the work of any particular individual as realistic or idealistic according as the treatment shows more prominently one tendency or the other. There are three ways in which these different tendencies, or attitudes of mind, are shown in the fine arts and literature. In the choice of a subject matter, the realist selects either something actually existing, some familiar scene, or well known event, or at least, if he does not make an exact transcript of a particular object or set of occurrences, it is the concrete individual things of experience with which he deals. Idealism, aiming more directly at the representation of what is universal and typical, constructs for itself its forms and matter, choosing to express itself through a representation it may be, of angels, Graces, or Madonnas, or through a literary portrayal of events and occurrences of some past time that admits of free imaginative treatment. This difference in choice of subject matter also carries with it important variations in manner of portrayal. As realism aims more directly than idealism at correspondence with nature, it is clear that it must emphasize to a greater extent fulness and accuracy of detail. But there is also a difference in the kind of detail that is chosen, and in the emphasis that is given to details of different characters. As it is the object of realism to represent its subject matter in concrete, individual form, the details which are essential to produce this impression are naturally emphasized. An idealistic treatment, on the other hand, seeking to represent more directly the universal and essential, necessarily gives an entirely different value to the various details, omitting, it may be, much that would be regarded as essential in the school of realism, and giving a prominent place to what the latter might keep in the background. It is false art and a false realism, however, that emphasizes what is ugly, unpleasant, and pathological in such a way as to make these the most prominent features of the total work. This *réalisme* has rightly been held to be characteristic of a decadent art, of an art that is inevitably suicidal. For the real, which it is the business of art to reveal and portray, in nature and in human nature alike, is the universal, the abiding, and hence the normal; for what is diseased and monstrous are necessarily particular and transient. Art, like all conscious activity, can only live so long as it assumes that what is rational in the fullest sense must be real.

J. E. CREIGHTON,

Professor of Philosophy, Cornell University.

Realschulen, rā-āl'shoo-lēn, a class of institutions in the German system of secondary education characterized by the emphasis laid upon the study of the sciences, mathematics, and modern languages as opposed to the gymnasias in which the classics constitute the principal feature of the curriculum. The Realschule took its rise in Germany in the early part of the 18th century, but did not attain its full development until the second half of the 19th century, when the tremendous progress of science compelled, after a long struggle, the recognition of this type of school as of equal rank with the gymnasias in the national system of education. In the struggle, however, between the classical school and the scientific school a mixed form was developed, approaching more nearly to the Realschule in the importance attached to the non-humanistic branches, but including Latin in its lists of studies. This type of school is known as the Real-gymnasium, and between it and the gymnasium the differences are growing less every year, especially since the study of Greek in the Prussian gymnasias was rendered non-obligatory in 1900. Real-gymnasias are, however, included under the general designation of Realschulen, a term which, in its broadest signification, includes the following classes: (1) *Oberrealschulen* (Upper Real Schools), scientific schools with a nine years' course, giving no instruction in the ancient languages; (2) *Realgymnasien* (Real-gymnasias), scientific schools with a nine years' course, giving instruction in Latin; (3) *Realschulen* (in a stricter sense), the same as the *Oberrealschulen*, without the highest class, giving thus a seven years' course; (4) *Realprogymnasien*, bearing the same relation to the *Realgymnasien* as the *Realschulen* to the *Oberrealschulen*; and (5) *Höhere Bürgerschulen* (higher middle schools), offering a six years' course without Latin. While the Real-gymnasium has been approaching the classical schools in character, the Real-schools proper have been extending their scope so as to include various forms of technical and even industrial education. Graduates of Real-schools are ineligible for admission to various departments and faculties in the universities, the most liberal conditions prevailing in Prussia, where only the faculty of theology is closed to them.

Realty and the terms real property and real estate denote the interest one has in lands; it applies not only to ground but to everything which is attached or a part of it, as trees, stones, houses, or other structures. Timber, grain, and grass rooted to the soil are realty, though when severed they become personalty. Any crop which is an annual product of the soil when ripe is considered as personal property. Permanent buildings erected on one's land without permission become the property of the owner of such land, without regard to the ownership of the materials. Fixtures or things which have been attached to the realty and can-

not be removed without injury to it, or which have become so adapted to the building or land as to be necessary to its use, are considered a part of the realty. In addition to the elements of realty which have been above described, are rights which are connected therewith, such for example, as a right of way, a right to the use of water course and easements. An uninterrupted use of any easement or right for 20 years, or any less period fixed by statute raises presumption of title. The various estates which one may possess in realty had their origin in the feudal system of England, the fundamental principle of which is that the king was the original proprietor of all the land in his kingdom, and no one came into any part of it except by gift from him, or in return for feudal services, and thus the land was divided among a graded body of owners beginning with the king's noblemen. In the United States all the instances of feudal tenure have been abolished. In Canada the tenure by which land is held varies in the different provinces, some being largely regulated by a statute enacted during the reign of George III.

Title has been defined as a means whereby the owner of lands has the just possession of his property; title may be acquired by descent, that is, through the death of an ancestor, by purchase, or by operation of law. The legal title of land is usually transferred from one person to another by means of a deed, the many essentials of which are fixed by the statutes in various jurisdictions.

Ream's Station, Battle of. As the extension of Gen. Grant's left to Globe Tavern on the Weldon Railroad (see **GLOBE TAVERN, BATTLE OF**) did not prevent Gen. Lee's use of the road as a line of supply up to a point within a day's wagoning to Petersburg, Gen. Grant determined to destroy the road as far down as Rowanty Creek, 13 miles beyond Globe Tavern. On 22 Aug. 1864 Gen. Hancock, with Miles' and Gibbon's divisions of the Second Corps and Gen. Gregg's cavalry division, in all about 8,500 men, moved to the left, and by night of the 24th had destroyed the road from Globe Tavern to a point three miles south of Ream's Station, and 12 miles from Petersburg. During the 24th Gregg's cavalry was sharply attacked by Gen. Butler's division of Confederate cavalry, and at night Gen. Meade informed Hancock that Confederate infantry was moving in his direction, but as yet none had been seen by Hancock. At daylight of the 25th a cavalry reconnoissance drove in the Confederate pickets, and Gibbon was ordered to move out from Ream's Station and complete the destruction of the road. Gibbon had hardly gotten well on the road, when the Union cavalry was driven in by cavalry supported by infantry, and he was obliged to deploy a strong skirmish line to check the enemy in pursuit. Prisoners taken from three of Gen. A. P. Hill's divisions showed that the Confederates were in strong force and Gibbon was ordered back to the Ream's Station intrenchments, where he arrived at 10 A.M. and united with Miles' division. The intrenchments were very light and had been hurriedly thrown up by Gen. James H. Wilson in his cavalry fight near that place late in the preceding June. They ran along the railroad about 700 yards and then

were drawn back on the right and left about 800 or 900 yards, at nearly right angles. Both flanks were exposed to reverse fire from the front. Miles held the right half of these works, Gibbon the left half. Gregg's cavalry held the approaches in the direction of Petersburg and Dinwiddie Court House. When Hancock's movement became known to the Confederates Gen. A. P. Hill, with the larger part of his corps, together with G. T. Anderson's brigade of Longstreet's corps and Gen. Wade Hampton's two cavalry divisions, marched to prevent the destruction of the railroad, and at 2 P.M. of the 25th Gen. Wilcox's division made two attacks upon Miles, which were repulsed, leaving killed and wounded within a few yards of Miles' front. At 5 P.M. Hill opened a heavy artillery fire and, at the end of 15 minutes, Gens. Heth and Wilcox, with five brigades and three regiments, made another assault upon Miles, and a part of his line, held by raw recruits, gave way, abandoning a battery. At the same time the right of Gibbon's line gave way and two more batteries fell into possession of the Confederates. Gibbon was ordered to retake his lost ground, but his troops, many of whom were new recruits and drafted men, responded feebly and fell back under the first fire. Miles rallied the 61st New York, and by desperate fighting retook a part of his line and his lost battery. Hampton's cavalry now attacked Gibbon and drove him entirely from his works, but was checked by a heavy flank fire from Gregg's dismounted cavalry, upon which Hampton turned on Gregg and forced him back to the left of a line which Gibbon had established a short distance in rear of the intrenchments from which he had been driven. An effort made to retake the intrenchments failed because of the inability of the Union commanders to induce their men to go forward. At dark Hancock withdrew from the field. Gen. Hill made no attempt to follow up his advantage, but returned to the Petersburg intrenchments, leaving Hampton's cavalry at Ream's Station. The Union loss was 669 killed and wounded, and 2,073 captured or missing, together with 12 stands of colors and nine guns. The Confederate loss, as reported by Hill, was 720, chiefly, if not entirely, killed and wounded. Rearick, Peter Anton, American naval officer: b. Maryland, 12 Nov. 1838; d. Washington, D. C., 9 Feb. 1901. He entered the navy in 1860, was appointed third assistant engineer, and served through the Civil War with promotion, becoming first assistant engineer in 1864. In 1874 he was made chief engineer and served in that capacity until 1900, when he was retired with rank of rear-admiral.

Reasoning, or Inference, is a mental process in which we advance from some known facts to the truth of some other fact which is different from the starting-point. The basis for the transition is always found in the knowledge from which we set out: this is taken or as-

sumed to be real, and in it is found the ground and justification for the advance to something else. The differentia of reasoning thus appears to be mediation; when we reason we infer that something is true because something else is true. Knowledge derived from reasoning may therefore be termed mediate, as opposed to the immediate knowledge obtained from sense perception and memory. The question at once arises how any mental content can justify an advance to something different from itself? How are we ever warranted in passing from the known to the unknown? This is not merely the question that Mill raised as to whether all syllogistic reasoning—all advance from premises to conclusion—was not a *petitio principii*; but it concerns all reasoning, inductive and deductive alike. The dilemma is that if the result is not contained in the starting-point the advance does not seem to be justified; if it is already present, the reasoning shows nothing new. The view of Leibnitz was that all reasoning is analysis, a drawing out and fuller explication of the original datum of the mind. Kant pointed out that thinking involves also synthesis, new constructions and additions to the material from which it starts, and he takes as the fundamental problem of his 'Critique of Pure Reason' the question, how such synthetic judgments are possible. His answer is essentially identical with that which Aristotle gave, namely, that the mind or reason (*νοῦς*) itself enters into the process as a premise—or, in other words, that it is through the creative activity of the mind that the new truth is reached. Whether or not one can connect one fact with another in a logical way depends upon one's intellectual ability to discover points of essential resemblance or identity between facts. The good reasoner is he who can look beneath the surface and detect identities that are not at once obvious, as Newton, for example, did when he reasoned from the fall of the apple to the movements of the heavenly bodies. Reasoning, then, may be defined as the process of discovering essential resemblances or points of identity between things.

It follows from what has been said that reasoning is not a process or function of mind that can go on apart from experience. The thinkers of the modern period down almost to the end of the 18th century, continued to believe that reason was a kind of special organ or faculty that could yield truth of the highest order of certainty quite apart from ordinary experience. It was Kant who first clearly and incontestably showed the impossibility of deriving knowledge from reason taken in abstraction from ordinary sense experience. Kant, however, uses the term Understanding (*Verstand*) for the thinking faculties as employed in interpreting experience, and reserves the name Reason (*Vernunft*) for the vain and illusory attempt of thought to operate in independence of any given material of experience. Apart from this terminology, however, which has not been generally followed, the result of Kant's teaching was to exhibit the close and essential connection that exists between thinking and sense-perception: on the one hand, thought is empty apart from the material of sense-perception, and, on the other, what we call ordinary perceptive experience is constantly interwoven with more or

less explicit processes of reasoning. Reasoning does not go on in a vacuum, nor is it a separate and distinct function of mind that in some mysterious way spins truth out of itself. But reason is on one side a universal function of receptivity; it receives its material from every channel of experience, and is itself just the unifying, co-ordinating, and systematizing life of experience. Deduction and induction are often spoken of as if they were distinct species of reasoning. Reasoning, however, is always one and the same process. It consists, as we have seen, in connecting parts of experience by the discovery of some identical element in them. This identity, as present in various particulars, we may speak of as a universal, or general principle, and therefore say that when we reason we unite particulars through a general law or principle. Now, the difference between deduction and induction is a difference in the starting-point and in the direction in which we proceed. If we are already in possession of the general law, and set out to apply it to particular cases, we are using deduction. If, however, our starting-point is the particular instances, then we reason inductively to discover the universal law of connection. In both cases the structure of the completed inference is the same, and consists in the connection of particulars, in virtue of our insight into the universal law or principle expressed in them.

In this reference to a universal principle, we have also that which distinguishes reasoning from the transition from idea to idea of the associative process. In a large part of the conscious life which usually is described as thinking, one idea by its very presence seems to call up another, without the apprehension of any universal or essential law of connection. But this is mere drifting on the part of the mind. In reasoning the mind is fully awake; it sets a definite purpose before it, and proceeds by active attention and analysis to discover essential and necessary points of connection. It thus uses association for its own purposes; so that if we define reasoning as a process of association, we must add that it is association guided and controlled at every step by the purposes of thought itself. How conscious and explicit must this direction be before we can call the process reasoning? Can animals properly be said to reason? These questions do not admit of any off-hand answer. The conscious direction of the mind, the clearness with which it apprehends the universal in the particular, is a matter of degree. We may say that some direction on the part of the mind then must be, as well as some apprehension of the terms as universal, if reasoning is to occur, without attempting to determine just when these conditions are fulfilled in any individual mind or in any species. What we call conscious reasoning, is doubtless continuous with associative and instinctive mental processes that seem entirely mechanical and irrational, and the connection between the two extremes may be mediated by actually observable processes. This continuity, however, gives no justification for refusing to regard the differences as important, or for explaining either extreme of the process in terms of the other. See DEDUCTION; INDUCTION; LOGIC.

J. E. CREIGHTON,
Professor of Philosophy, Cornell University.

Réaumur, rā-ō-mūr, **René Antoine Ferchault de**, French physicist: b. La Rochelle 28 Feb. 1683; d. La Bermondiere, Maine, 17 Oct. 1757. He studied under the Jesuits at Poitiers, and afterward at Bourges, and went to Paris in 1703. His relative, the president Hénault, introduced him to the savants of the metropolis, and in 1708 he was chosen a member of the Academy of Sciences, to which he had presented some memoirs on geometry. For nearly 50 years he continued to be one of its most active members, his labors embracing the arts, natural philosophy, and natural history. He was appointed to assist in the 'Description des Divers Arts et Métiers,' published by the Academy, and in executing his part of the undertaking pointed out the way to various improvements by the application of the principles of physics and natural history. He made important observations on the formation of pearls, and discovered that the "turquoises" of Languedoc consisted of the fossil teeth of extinct animals; but among his most useful researches must be reckoned those of which he gave an account in his 'Traité sur l'Art de Convertir le Fer en Acier, et d'Adoucir le Fer Fondu' (1722), in which he first made known in France the process of manufacturing steel. He received therefor a pension of 12,000 livres (about \$2,400). As a natural philosopher he is principally celebrated for the invention of an improved thermometer, which he made known in 1731. (See THERMOMETER.) The fabrication of porcelain also occupied much of his attention, and led him to the discovery of a kind of enamel, called the porcelain of Réaumur, in 1739. His 'Mémoires pour Servir à l'Histoire des Insectes' (1734-49) places him in the first rank of modern naturalists. In it he demonstrated, among various things, the correctness of Peyssonnel's assumption that corals are not plants, but animals.

Reavis, James Bradly, American lawyer and jurist: b. Boone County, Mo., 1848. He entered Kentucky University, but did not complete the course, was admitted to the bar in Hannibal, Mo., in 1872, and for two years was editor of the *Monroe City Appeal*. In 1874 he removed to the West, finally settling in Washington Territory, where he established a law practice. He was a member of the upper house of the territorial council in 1888, and a regent of the territorial university, until Washington became a State. In 1889 he was an unsuccessful candidate for supreme judge, and from 1896 to 1902 was chief justice of the Washington supreme court.

Rebaptizers, those who taught that the repetition of baptism was under certain circumstances imperative. The term is specifically used of the Baptists who enforce rebaptism in the case of all who have not been baptized by immersion. Views with regard to rebaptism have been varied. Many early Christians declared it unnecessary even for one who had been baptized by an unbeliever, or by a child in play. In doubtful cases the hypothetical or conditional form was enjoined, as in the Book of Common

Prayer, and in accordance with the decretal of Alexander III. (1159-81).

Re'bec, or **Rebeck**, a stringed musical instrument of the violin kind, said to have been introduced by the Moors into Spain. It soon became popular all over the Continent, being the favorite instrument of minstrels, and of village musicians, and up till the end of the 17th century, playing the same important part at fairs, rustic games, and weddings as does the violin at the present day. It was somewhat larger than the latter instrument, but had only three strings, which were tuned in fifths, and rubbed with a bow. The neck of the rebec terminated in a more or less grotesque representation of a human head.

Rebecca, a character in Scott's 'Ivanhoe', daughter of the Jew, Isaac of York. She falls in love with Ivanhoe and nurses him after the tournament of Ashby, and he in turn saves her life by appearing as her champion in the lists after she has been convicted of sorcery and condemned to be burnt at the stake. She departs from England with her father to live in Spain.

Rebec'caites, or **Rebekah's Daughters**, a singular association formed in South Wales, in 1839, for the destruction of turnpike-gates and toll-houses. The rioters were generally dressed in women's clothes, under a leader in the same guise, and made their attacks by night on horseback. The curious appellation by which they designated themselves was derived from the scriptural passage regarding Rebekah—"Let thy seed possess the gate of those who hate them." Successful for a time they were emboldened to greater lawlessness, and were attacked and dispersed by the military.

Rebekah Lodges. See ODD FELLOW.

Rebel Yell, the cry of the Confederate troops as they rushed to battle in the Civil War, although as a matter of fact, they frequently shouted the names of their States, as "On Virginia!" "On North Carolina!"—and so forth. It is difficult to interpret the rebel yell in written language. It was very different from the full-toned hurrah of the North, being more like a shriek. Near the crisis of a charge, the men would change from a double-quick to a mad rush, wildly yelling, "Y-Yo Yo—Wo-Wo," for the triple purpose of encouraging each other and confusing and terrorizing the enemy.

Rebellion, an uprising with force and arms against established authority. A rebellion may be an armed outbreak for the purpose of obtaining the redress of a grievance, or preventing the enforcement of an obnoxious law, Shays' Rebellion in Massachusetts having been an example of the former, and the Pennsylvania Whiskey Insurrection of the latter. Rebellion of a more formidable character is that which attempts to establish a new and independent organization in place of the existing government. Such was the American Revolution, and such also was the unsuccessful attempt to perpetuate the Southern Confederacy. Old World rebellions have been chiefly dynastic at least up to the 19th century—that is, wars between reigning families, and others, usually akin to them, which claimed the right to rule. The rebellion against Charles I. of England was of a different character, being prompted by aspirations for civil liberty and religious reform. The expulsion of James II.

REBELLION — RECAPITULATION

was of a similar motive, and the American Revolution was a struggle for the inalienable rights of man.

In former ages, and up to a very recent period, conquered rebels were treated with great severity, being put to death, maimed, or enslaved. In partly civilized countries such as China rebels are treated even now with the greatest cruelty. The more advanced nations, however, while retaining on their statute books the Draconic code of times gone by, treat beaten insurgents with leniency. After the downfall of the Southern Confederacy the only penalty inflicted was the disfranchisement for a time of the leaders of the rebellion, all being eventually admitted to the full rights of citizenship. British subjects who took sides with the Boers in the late South African war were, when convicted, imprisoned for short terms and disfranchised, although most of them probably escaped all punishment.

With the extension of suffrage came a consequent ability of the people to secure redress of wrongs without resort to violence. The causes which provoked rebellion in olden times are disappearing, while, apart from Carlist insurrections in Spain, there have been no dynastic rebellions in Europe for many years past.

Rebellion, War of. See CIVIL WAR IN AMERICA.

Reber, rā'bēr, Franz von, German art-historian: b. Cham, Bavaria, 10 Nov. 1834. He studied in Munich, Berlin, and Rome, became a lecturer at the University of Munich in 1858, was appointed professor at the Polytechnicum there in 1863, and in 1869 occupied the chair of history of art in that institution. In 1873 he became director of the Royal Gallery. He has translated Vitruvius' 'Architecture' (1865) and Rooses' 'History of the Antwerp School of Painting' (1880), and has written: 'Geschichte der Baukunst im Altertum' (1864-7); 'Kunstgeschichte des Mittelalters' (1886); 'Geschichte der Malerei vom Anfang des 14. bis zum Ende des 18. Jahrhunderts' (1894); 'Die phrygischen Felsendenkmäler' (1897); etc.

Reber, rā-bār, Napoleon Henry, French composer: b. Muhlhausen, Alsace, 1807; d. Paris 1880. After studying with Reicha and Le Sueur, he wrote chamber music of remarkable merit, and in 1851 was appointed professor in the Conservatory, and succeeded Halévy in the chair of composition 1862. Among his works are: 'Le Diable Amoureux' (1840), a ballet; 'Le Nuit de Noël' (1848); 'Le Père Gaillard' (1852); 'Les Papillotes de M. Benoist' (1853); and 'Les Dames Capitaines' (1857), all four comic operas. He has also produced some instrumental work of a high order — four symphonies, one overture, one series for the orchestra, three stringed quartets, one stringed quintet, one pianoforte quartet, seven pianoforte trios, and miscellaneous pieces. His 'Traité d'Harmonie' (1862) is a standard work.

Rebis'so, Louis T., American sculptor: b. Italy 1837; d. Norwood, near Cincinnati, Ohio, 3 May 1899. At 20 he joined in Mazzini's attempt to establish an Italian republic (see MAZZINI, G.), and was obliged to leave Italy. Taking refuge in the United States, he settled in Boston, Mass. Subsequently he went to Cincinnati, Ohio, where his fame as an artist de-

veloped. His leading works are the equestrian statues of Gen. McPherson in Washington, D. C.; of Gen. Grant in Lincoln Park, Chicago, and of Gen. W. H. Harrison in Cincinnati.

Re'bus, a mode of expressing words or phrases by pictures of objects whose names bear a resemblance to those words, or to the syllables of which they are composed. Many of the ancient coats of arms were rebuses on the names of those who bore them; thus a lock and a heart for the name of Lockhart, an eye and a ton (a barrel) for that of Eyton, etc. In heraldry, a rebus is a device intended to represent a proper name by a picture; a bearing or bearings on a coat of arms, containing an allusion to the name of the owner; as in the coat of the family of Arches, which consists of three arches, two simple and one double, borne on a shield; and that of the Dobell family, who bore on a sable shield a doe passant, between three bells argent.

Recall. See REFERENDUM.

Récamier, rā-kā-mē-ā, Jeanne Françoise Julie Adelaïde Bernard, French social leader: b. Lyons 4 Dec. 1777; d. Paris 11 May 1849. She was educated at the convent of La Deserte. At 16 she went to Paris, whither her father, a wealthy banker, had transferred his business. Her extraordinary beauty and talents brought round her shoals of suitors belonging to the world of letters, finance, and politics, and in 1793 she was married to Jacques Récamier, a rich banker, more than double her own age. The Récamier salon was long filled with many of the celebrities of the day. Though she wrote nothing, she, by her confidential intercourse with Chateaubriand and others, exercised no slight influence on French literature. Under the Empire she was opposed to Napoleon, as he had placed her father under surveillance for his royalist tendencies, and Napoleon took his revenge by refusing to support the bank of her husband during a crisis. It accordingly failed, and Madame Récamier was obliged to quit Paris. She took up her residence with her friend Madame de Staël at Coppet, and afterward traveled, like her, till the downfall of Napoleon, when she again opened her salon in the Abbaye-aux-Bois at Paris. Her 'Recollections and Correspondence' appeared in 1859.

Recapit'ulation, or Biogenetic Law, in zoology, terms applied to the parallel which exists between the embryonic development of an individual animal (ontogeny) and the historical evolution of its race (phylogeny). This parallel is explained by the theory of evolution (q.v.), according to which, in the words of Sidgwick, "the developmental history of the individual appears to be a short and simplified repetition, or in a certain sense a recapitulation, of the course of development of the species." This class of facts was recognized more or less completely by the earliest naturalists, and were extensively studied and formulated by Von Baer and Agassiz previous to the explanation of them by means of the doctrine of descent; but it should be added that obscurities still exist, concerning the explanation of which embryologists are in doubt or at variance. Examples may be found in the embryological development of all vertebrates. Thus the frog develops through stages in which the embryo just before hatching is very fish-like, after hatching becomes a tad-

pole which exhibits many newt-like characters; and finally reaches the permanent frog stage. This accords with the comparative rank of the fish, newt and frog groups in classification; and also with the succession appearance of these groups. Man, as the highest animal, exhibits most completely these phenomena. In the earliest stages the human embryo is indistinguishable from that of any other creature. A little later the cephalic region shows gill-slits, like those which in a shark are a permanent feature, and the heart is two-chambered or fish-like. Further development closes the gill-slits, and the heart changes to the reptilian type. Here the reptiles stop, while birds and mammals advance further; but the human embryo in its progress to the higher type recapitulates and leaves features characteristic of lower mammalian forms — for instance, a distinct and comparatively long tail exists. Most of these changes are completed before the embryo is six weeks old, but some traces of primitive and obsolete structures persist throughout life as “vestigial” or “rudimentary organs,” and others appear after birth in infancy, as the well-known tendency of babies to turn their feet sideways and inward, and to use their toes and feet as grasping organs, after the manner of monkeys. This recapitulation of ancestral characters in ontogeny is not complete, however, for not all the stages are reproduced in every case, so far as can be perceived; and it is irregular and complicated in various ways, among others by the inheritance of acquired characters. The most special students of it, as Haeckel, Fritz Müller, Hyatt, Balfour, etc., distinguish two sorts of recapitulation “palinogenesis” and “cenogenesis,” the last manifested most completely in the metamorphoses of insects. See EMBRYOLOGY, and consult authorities mentioned thereunder.

Receipt, in law, a written document, declaring that certain goods or a sum of money have been received. When made out in full, a receipt should contain (1) the date when the merchandise or money was received, (2) the name of the person or firm from whom received, (3) the name of the person who received it, and (4) for what the money is paid or deposited. A receipt may be in full or in part payment of an account, and operates accordingly. A receipt, though evidence of payment, is not absolute proof, and this evidence may be rebutted by proving that it was given under misapprehension.

Receiver, in law, is an officer of the court through whom the court, on account of its jurisdiction, takes possession of property which is the subject of a suit, for the purpose of preserving it from injury or loss, secures the proceeds and finally disposes of them according to the rights of all parties interested. Receivership is a remedial agency for the purpose of preserving the property in question from waste, destruction or deterioration pending litigation; it is auxiliary to the main action. It is a remedy which originated in the English Court of Chancery and is purely equitable. Under the existing English law, and also that in Canada, a receiver may be appointed when the court deems it just or convenient. In the United States, courts of equity have general authority to appoint receivers, and in most States by statutory provision. The courts are generally disinclined to appoint

a receiver, except that from all the circumstances it appears essential for the purpose of the preservation of the property in controversy. Technical injuries and circumstances which are doubtful are insufficient. A receiver will be appointed to prevent a fraudulent transfer, or possession of property, or for the protection of estates, or of property of a partnership where dissolution is desired and the partners cannot agree; of mortgaged property, foreclosure proceedings, corporations which are insolvent, or which are fraudulently managed. The appointment of a receiver rests entirely within the discretion of the court to which the application is made, and the court also has discretion as to its choice of receiver. One will not be appointed a receiver who is not qualified to perform his duties, and he must be impartial, independent and disinterested. A corporation may be appointed a receiver if authorized by its charter. In order to obtain a receiver one must show the right to the property, or a lien upon it, or that the property in question was obtained by fraud, or is in danger of loss from waste, or the misconduct or insolvency of the party in possession, and the circumstances must show extreme necessity. A receiver is created by the court whose officer he is and is under its control, supervision, and protection. His duty is purely ministerial and the utmost good faith is required of him; his acts should be with the general or special authority of the court and must be without discrimination for the interests involved. A receiver may employ counsel, agents and assistants, make necessary repairs, pay taxes and bring suits; he must keep the property insured and is required to give a bond for faithful performance of his duty. He takes complete possession of the property at the time when appointed; his liability is generally official, and he is responsible to any person who sustains loss through his negligence or misconduct in relation to his trust; he is entitled to a compensation for his services, which is in some jurisdictions fixed by statute, in others by the discretion of the court.

Recent Period, that division of the geological time-scale including the most recent portion of geological history. It is usually thought of as beginning with the appearance of man on the globe and running down to the present, and is therefore sometimes called the Human Epoch. It follows immediately upon the Pleistocene Period (q.v.) and is treated as a subdivision of this by some geologists, while others group Pleistocene and Recent under the Quaternary Period (q.v.). See GEOLOGY.

Rechabites, rēk'a-bīts, members of a kind of religious order in ancient Israel whose rule was in some respects like that of the Nazir or Nazarites: like them they were bound by vow to abstain from the use of wine. In their contempt for luxuries and the ways of settled life, they chose to live in tents rather than houses, and refused to sow grain or plant vineyards; their ideal was the nomad patriarchal life amid their flocks. The order had its origin in the northern kingdom of Israel, and was founded by Jonadab or Jehonadab, son of Rechab (whence the name Rechabites), in the reign of Jehu, king of Israel (2 Kings x.). After the fall of the kingdom of the North a body of the Rechabites entered the kingdom of Judah and

continued to live apart from cities and towns till at the approach of Nebuchadnezzar they took refuge in Jerusalem. Independent Order of Rechabites is the style of a total-abstinence beneficial society founded in England 1835 and of which a branch was instituted in the United States 1842. In 1902 the order had 270,000 members and the disbursements of the previous fiscal years were \$793,682; in the United States the Rechabites had three "tents," 35 "sub-tents."

Recife, Brazil. See PERNAMBUCO.

Recip'ocal, in grammar, reflexive. Applied to verbs which have as an object a pronoun standing for the subject; as, "Bethink yourself." It is also applied to pronouns of this class. As a noun, that which is reciprocal to another thing. Specifically, in mathematics, the quotient resulting from the division of unity by the quantity. The reciprocal of a vulgar fraction is the denominator divided by the numerator.

Reciprocity. See UNITED STATES, RECIPROCITY.

Recitative, rĕs'ĭ-ta-tĕv' (Italian, *recitativo*), a species of musical recitation, forming the medium between song and rhetorical declamation, and in which the composer and performer, rejecting the rigorous rules of time, endeavor to imitate the inflections, accents, and emphasis of natural speech. Although the rules of time and rhythm are not strictly observed, recitative is written generally in common time, in order to facilitate the reading. In its approach to speech, therefore, recitative is mostly syllabic song, that is, each syllable has generally but one tone, and the tones themselves are less prolonged than in *song* strictly so called. Hence recitative has not a distinct, developed melody, and a regular modulation; it may, according to the meaning of the words, pass with comparative freedom through the various tones. On the other hand, the tones of recitative are generally musical tones, of distinct height or depth generally, because in *recitativo parlante*, in the *opera buffa*, the tones become closely allied to those of speech. When recitative approaches still more to strict song, in respect to time and melody, the *arioso* originates. In short recitative may be called *declamation in musical tones*. Recitative includes the simple (by some also called the *parlante*) and the accompanied, or more properly, the *obbligato*. In simple recitative accompaniment also takes place, but it consists only in simple chords, which are given continuously, or interruptedly. In the *obbligato* recitative the instrumental accompaniment is of more importance, and consists of either sustained chords by the greater portion of the orchestral instruments, or even of florid passages. In the recitative much is left to the singer in respect to time, rhythm, and melody, which require much musical judgment and knowledge of harmony, in order to agree with the *obbligato* accompaniment. Peri Caccini and Monteverde are celebrated as having introduced the modern recitative. See OPERA.

Recke, rĕk'ĕ, Ernst von der, Danish poet: b. Copenhagen 14 Aug. 1848. His first work was a lyrical drama, 'Bertram of Born' (1873), performed with great success at the Theatre Royal at Copenhagen. Following this came 'King Liuvigild and his Sons' (1878), a

tragedy; a dramatic poem 'Archilochus' (1878); 'Knud and Magnus' (1881), a tragedy; 'Fru Jeanna' (1891), a tragic opera; and the 'Duchess of Burgundy' (1891). Between 1876 and 1890 he published several collections of lyrics and in 1881 a great work representing six years of labor in a field in which he is a recognized master, 'Principles of Danish Versification as Manifested in his Historic and Systematic Development.' Besides writing books for children he has published translations of Bornier's 'La Fille de Roland' (1876) and Rostand's 'Les Romanesques' (1896).

Recklinghausen, rĕk'ling-how-zĕn, Prussia, in the province of Westphalia, 15 miles north-west of Dortmund. It has good Catholic and Protestant schools. Its manufactures include damask, wicks, tobacco, and bricks. There are coal mines in the vicinity. Pop. (1900) 34,042.

Réclus, Jacques Elisée, zhăk â-lĕ-ză râ-klÿ, French geographer: b. Sainte-Foy-la-Grande, in the Gironde, 15 March 1830; d. Brussels, Holland, 4 July 1905. After being educated in the college of his native town and at the University of Berlin, he traveled in Germany, England, Ireland, and America. In 1859 he began to contribute to the 'Revue des Deux Mondes' articles on geography, geology, literature, politics, social economy, and other subjects, and also became associated with several geographical journals. During the siege of Paris and the Commune he was a member of the National Guard. Captured early in 1871 he was condemned to deportation, but his sentence was commuted to exile, and he spent some years in Italy and Switzerland. In 1883 the Tribunal at Lyons passed sentence upon him and Prince Kropotkin as being anarchistic leaders associated with the International Workingmen's Association, but Reclus escaped punishment by his absence from the country. In 1892 he was appointed professor of comparative geography in the free university of Brussels. His greatest work is his 'Nouvelle Geographie Universelle: La Terre et les Hommes' (1875-94), a splendid monument of the best geographical learning of our time. There is an English translation by Ravenstein and Keane (1887 onward). His other works include: 'La Terre: Description des Phénomènes de la Vie du Globe' (1867-8), translated into English as 'The Earth' (1871); 'Histoire d'un Ruisseau' (1869); 'Nice, Cannes, Antibes, Monaco, Menton, San Remo' (1870); 'Les Phénomènes Terrestres: Les Mers et les Météores' (1873); 'Histoire d'une Montagne' (1880), translated as 'The History of a Mountain' (1881); and 'L'Evolution, la Révolution et l'Idéal Anarchique' (1898), treating of his social philosophy.

Recognition Marks. See COLORATION, PROTECTIVE.

Recog'nizance, or **Recognisance**, in law, an obligation of record, which a man enters into before some court of record or magistrate duly authorized, with condition to do some particular act; as, to keep the peace, to pay a debt, or the like.

Recollet, rĕk'ô-lĕt, or **Recollect**, the name given to certain reformed bodies of the Franciscan and other orders in the Roman Catholic Church. The reformed society was founded in Spain by Juan de la Puebla y Sotomayor, conde

de Belalcázar, in 1484, was admitted into Italy in 1525, and into France in 1595. Thence they spread rapidly into Belgium and Germany. In France, before the Revolution, they had 168 houses, forming seven provinces, under the direction of the general of the Cordeliers. The order still exists at Medina, Sidonia, León, and Pamplona. It is also known as the Friars Minor of the Strict Observance of St. Francis. See also **ORDERS, RELIGIOUS**.

Reconcentrado, rē-kōn-sēn-trā'dō, a Spanish term applied to the inhabitants of the rural districts of Cuba, whose sufferings, caused by their treatment at the hands of the Spanish authorities, had much to do with provoking war between the United States and Spain. Governor-General Weyler issued a decree that all of the peasant class not actively engaged in the insurrection but at their homes or ranches, should be "reconcentrated" in or near certain towns, disobedience to this degree incurring the penalty of death. Accordingly, these people, non-combatants and mostly old men beyond the ability of army service, feeble old women, children, and babies, were forced to leave their homes and to gather in herds in and near these towns, where they were without food and shelter, "reconcentrated," to starve and to suffer from exposure to the weather and lack of all comfort. These helpless victims were called "reconcentrados." General Weyler's purpose was to desolate the island in certain parts so that the insurgents could not get aid and food. With this end in view, the abandoned homes were destroyed and whatever remained of value to the Spaniards was confiscated. Whole districts in the most productive part of the island were thus laid waste. Sugar mills were burned and other industrial property was destroyed. Nearly 400,000 "reconcentrados" were forced to go within the Spanish lines, where no means of subsistence were provided for them. More than 200,000 died of starvation and disease, an appalling record in modern civilization. When the decree, under General Blanco, was issued to permit the reconcentrados to return to their homes, there was but desolation where their homes had been. It was at this time that the American relief work, Red Cross ministrations, and other help availed this helpless class, but not to the full extent of their capacities till the American army and navy had driven Spanish rule from Cuba. The British followed a similar course in the Boer war, but with much less inhumanity.

Reconnaissance, rē-kōn-ā-sans, usually the examination of a territory, district, etc., or of an enemy's position, for the purpose of directing military operations. Also the preliminary examination of a county or district in reference to its general natural character, preparatory to a more particular survey for the purposes of triangulation or the construction of public works, as of a road, canal, railway, etc.

Reconstruction. See **UNITED STATES, RECONSTRUCTION**.

Record includes anything which is set down in writing for the purpose of preserving memory, and may be of a public or private nature. A record in a law suit is a complete written history of it from its beginning to its determination made by an officer duly authorized. All books and memorials kept by public

officers in accordance with the law, or which are connected with the proper discharge of their duty, are regarded as public records, as are also copies of papers which statutes require to be filed in public places. Generally anyone has a right to inspect public records, and in many jurisdictions the removal of public records is regulated by statute, some of which hold that to destroy, or remove, or injure the records is a criminal offense.

Record, rēk'ōrd. **Robert**, English mathematician b. Tenby, Pembroke, about 1510; d. London 1558. He studied at Oxford, was elected to a fellowship of All Souls' in 1531, studied, and probably taught, mathematics and medicine at Cambridge, and later was instructor in a variety of subjects at Oxford. Having gone to London, he became, it is said, physician to Edward VI. and Queen Mary. In 1551 he was made general surveyor of the mines and money; but despite this post seems to have been imprisoned for debt in King's bench prison, where he certainly died. Among his works were: 'The Grounde of Artes' (1540-1699); 'The Urmal of Physick' (1547), a comprehensive treatise on medicine; 'The Pathway to Knowledge, or First Principles of Geometry' (1551-1602); 'The Whetstone of Witte, or the Second Part of Arithmetike' (1557), the former a treatise on geometry, the latter on algebra; 'The Castle of Knowledge, a Treatise on Astronomy and the Sphere' (1551). For over a century his mathematical works were used as text-books in the schools of England. He was the first to use the sign = for equality, and to discover the method of extracting the root of multinomial algebraic expression.

Recor'der, in New York, the title of one of the criminal judges. The title is of ancient English derivation, the recorder in England being a person associated with the mayor and other magistrates of any city or borough, having jurisdiction in a court of record, for their better direction in matters of justice and proceedings according to law. The title of recorder is also given in some American States to an official having charge of real estate and other records.

Recorder, an obsolete musical instrument, formerly popular, resembling a flageolet in shape, with a mouth-piece like a bird's beak. The instrument was wider in the lower half than in the upper; its tones were soft and pleasing and an octave higher than the flute. Milton speaks in his 'Paradise Lost' of

The Dorian mood
Of flutes and soft recorders;

and it is also mentioned by Shakespeare in 'Hamlet.'

Recreation Piers, piers on the river-front in several of the large American cities maintained as places of recreation for the people, and usually crowded on warm nights in the summer months by those who cannot afford to go out of the city to summer resorts. Music is furnished at the public expense, and order is maintained by the police. Standing forth preeminent and as the leader among the cities providing such breathing-places for the poor is New York City which in 1903 had seven, three located on the East River and three on the North River, Manhattan, and one in Brooklyn, two of which are also open in winter.

Rec'reative Religionists, the name of an association formed in London 1866 for the pur-

RECRUITING — RECTUM

pose of providing on Sunday evenings popular lectures on scientific subjects with sacred music at intervals. An effort was made to suppress the work of the association under the provisions of the "Sunday Act," 21 Geo. III. ch. 49, but it failed, and the Recreative Religionists or Sunday Lecture Society now figures in the registrar-general's report among "sects having registered places of worship."

Recruiting. See REGULAR ARMY.

Rectangle, in geometry, a parallelogram or quadrilateral figure whose angles are all right angles. An equilateral rectangle is a square. A rectangle is said to be contained by any two of the sides about one of its angles; thus, if A B and B C represent two adjacent sides, the rectangle is said to be contained by A B and B C, or, as it is sometimes expressed, it is the rectangle under A B and B C. The area of a rectangle is equal to the product of its base and altitude. Rectangles having equal bases are to each other as their altitudes: rectangles having equal altitudes, are to each other as their bases.

Rectify, to refine common alcohol or spirit by distillation. The process of rectifying begins after the spirit itself has been distilled, and consists in removing the impurities from the spirit by fractional or repeated distillation, so far as possible, for it is impossible in this way to get rid of fusel oil. Whiskey, brandy, and rum, if genuine, are made from rectified spirit. See DISTILLED LIQUORS.

Rector, in the Protestant Episcopal and Roman Catholic churches, is the clergyman who has the complete charge and care of a parish church. The term rector is also applied in some monastic orders to the chief officer of a convent; and again to designate the heads of universities, colleges, academies, schools, and other educational corporate establishments.

Rectum, the lower portion of the large intestine or colon. The term, however, is a misnomer so far as the human anatomy is concerned, for the bowel adapts itself to the curves of the sacrum, and at one point doubles upon itself. The rectum is from six to eight inches long, extending from the sigmoid flexure to the anus, and is narrowest at its two extremities. The largest and most dilatable portion (ampulla) just above the levator-ani muscle, forms a sort of pocket in which feces, etc., lodge. The rectum has a mucous coat (membrane), gathered into transverse folds (Houston's valves), forming compartment-like spaces; a submucous and a muscular coat; and at the upper portion, where there is little motion, a peritoneal coat (mesentery).

The tendency of specialists is to consider the rectum as only that part of the bowel below the third sacral vertebra, and devoid of mesentery, and to divide it into two portions, the fixed rectum and movable rectum. The rectum is in close opposition with large pelvic vessels and nerves and a portion of the small intestine; also, in the male, with the bladder, urethra, and prostate gland; and in the female, with the uterus, vagina, and Douglas' cul-de-sac. Its lower portion is surrounded by the hæmorrhoidal plexus of veins. The vessels forming this plexus, as also those of the vaginal and vesicoprostatic plexuses, are very large, frequently

communicate, and have many valves. It is in the lower portion of the rectum that hæmorrhoids or piles and many other painful affections occur, as blood-vessels and nerves are numerous, and the muscles powerful.

Diseases of the Rectum.—These include congenital imperfections. The rectum may even be absent, or partially developed, terminating in a blind pouch; or it may abnormally open into the bladder, vagina, uterus, or urethra. These imperfections can be usually remedied by the surgeon.

Threadworms or pinworms frequently inhabit the rectum and cause itching about the anus (*pruritus ani*). They may be destroyed by injections of lime-water or a solution of ox-gall. Abscesses (caused by blows, perforation, sitting upon cold, damp seats, etc.) may form in the loose areolar tissue about the lower part of the rectum and open externally or into the rectum, leaving a fistulous tract (*fistula in ano*). Benign tumors, fibroma, papilloma, and adenoma, and also carcinomatous and sarcomatous tumors may form in the rectum. Hæmorrhoids, due to disease or a weakened condition of the hæmorrhoidal veins, are common, especially in persons who are on their feet a large part of the time and who are engaged in sedentary occupation. Hæmorrhoidal affections may be relieved by astringents or by operation. Polypus of the rectum (soft and hard), comparatively frequent in childhood, is a tumor resembling in shape a berry or a pear, and having a peduncle. It sometimes bleeds and protrudes at the anus after stool. It is composed of elongated follicles and a network of small blood-vessels. It may be removed by a ligature or by an appropriate instrument. Prolapsus of the rectum, due to a relaxed state of the sphincter-muscles and the coats of the rectum, may be either incomplete or complete, with protrusion from the anus (*prolapsus ani*). It is observed generally in young children and women, and is brought on by bearing-down strains. Treatment requires the replacing of the bowel and keeping of it in place; and astringents, caustics, and operation are employed as may seem advisable. Stricture of the rectum, or narrowing of its calibre, may be very limited in extent, or may include a considerable portion of it, and is due usually to malignant or syphilitic ulceration. The symptoms include difficult defecation, more or less purulent and bloody discharges, and pain. If not relieved, it affects the general health. Treatment consists of dilatation with rectal bougies, or division of the cicatricial tissue by instruments (*colotomy*). Ulceration of the rectum may be due to simple inflammation or to dysentery, tuberculous disease, syphilis, or malignant disease. Symptoms vary with the character of the sores and their location. There are usually discharges of pus, blood, and mucus, and some pain and tenesmus. Treatment depends on the nature and extent of the disease and the constitutional condition of the patient. It includes the keeping of the bowel as quiet and free from fecal matter as possible, the use of simple food, saline aperients, and vegetable astringents, or nitrate of silver. Fissure of the anus, or a tear of its mucous membrane, may extend into the rectum, or a fissure of the rectum may exist by itself. In either case the fissure is

usually produced by the passage of hardened feces and the attendant straining. It is sometimes obstinate. Treatment calls for regulation of the bowels, dilatation, and the application of nitrate of silver or other astringent. Neuralgia of the rectum is sometimes mistaken (before an examination of the rectum is made) for fissure. Treatment as in other neuralgias, except when it is caused by pressure of a displaced coccyx upon sacral nerves. This bone must then be replaced or removed.

Intestinal calculi (enteroliths), gallstones, and faecal concretions containing, it may be, fruit-stones or berry-seeds, are occasionally found in the rectum. They give rise to more or less tenderness and abdominal pain, severe and intractable constipation, cold perspiration, vomiting, thready and rapid pulse, etc.; and they must be removed. Invagination or intussusception of the rectum, of the upper portion into the lower, as the result of strain and weakened rectal walls, requires surgical aid.

Regular and free movements of the bowels, unattended by straining, are of the greatest importance in the treatment of most rectal ailments, and preventive of many. The fact that the lower portion of the rectum is capable of holding a large amount of hardened faecal material, while the more liquid matter readily flows by it and out of the body, is not generally understood.

Recusants, rēk'ū-zants or rē-kū'zants, a term in use under the penal laws of England, when it was sought to force the consciences of the people by legal punishments. Recusants were those persons who refused or neglected to attend divine service on Sundays or holidays in the Established Church, or to worship according to its forms. The word is first met with in temporal courts in the first year of Queen Elizabeth, when it was enacted that all persons who, without reasonable excuse, failed to attend some usual place of prayer, should be censured and fined for every offense 12 pence. In 23 Elizabeth the fine was made for every month £20; and later in the same reign it was enacted that if recusants did not submit within three months after conviction they might, upon the requisition of four justices of the peace, be compelled to abjure and renounce the realm; and if they did not depart, or if they returned without due license, they were to be treated as felons, and suffer death without benefit of clergy. In the case of Roman Catholic recusants the laws were more severe. They were liable to a forfeit of 100 marks (£66, 13s. 4d.) for hearing mass; for saying it the fine was doubled, and in both cases they had to undergo a year's imprisonment. They were disabled from taking lands either by descent or purchase after the age of 18, unless they renounced their errors, and could not keep or teach schools under pain of perpetual imprisonment. After a first conviction, they could not keep arms in their houses, could not appear within 10 miles of London, could not travel five miles from home without license, could not hold any public office, could not have marriage, baptism, or burial performed, except by a minister of the Established Church; could not bring any action at law or equity, all under penalties of fine and imprisonment. By the Toleration Act (1 Wm. and Mary, ch. 18) all persons dissenting from

the English Church, except Roman Catholics and anti-Trinitarians, were allowed to meet for purposes of worship according to their own forms on taking the oaths of allegiance and supremacy. The act was extended to include Unitarians in 1813, and in 1829 the Catholic Emancipation Act granted toleration to Roman Catholics.

Red, one of the three primary colors. Mixed in equal strength and proportion with the other primaries, it yields secondaries, for example, with yellow it forms orange; with blue, violet, etc. Also a pigment. The most useful red pigments are carmine, vermilion (sulphuret of mercury), chrome-red, scarlet-lake (biniodide of mercury), madder-lake, light red, burnt sienna; these are yellow reds. Venetian red, Indian red (carbonate of oxide of iron), and crimson-lake are blue reds.

Red Admiral, a butterfly of the genus *Vanessa*, especially *V. Atalanta*, so called by British collectors. See ADMIRAL.

Red-backed Mouse, a small, chestnut-backed wood-mouse (*Evotomys gapperi*) closely related to the meadow-mouse, which is common throughout the eastern half of the United States and in the Saint Lawrence Valley, and has the general habits of a meadow-mouse.

Red-backed Sandpiper, the dunlin (q.v.).

Red Bank, N. J., town, in Monmouth County; on the Shrewsbury River, at the head of navigation, and on the Central of New Jersey, the New Jersey Southern, and the Pennsylvania R.R.'s; about 25 miles south of New York. It has regular steamer connection with New York, Atlantic Highlands, and other ports. Settlements were made in the vicinity in 1650, by English and Dutch colonists. It was incorporated as a town in 1872. It is an attractive residential town, and a favorite summer resort. It has a number of industrial establishments, chief of which are a large canning factory, carriage shops, clothing factory, boiler works, gold-beating works, and brush factory. About 500 persons are employed in the manufactories. The trade is chiefly in manufactures, farm products, and fruit. It has nine churches. The educational institutions are the Shrewsbury Academy, several private schools, a high school which cost \$60,000, public and parish schools, and a public school library. The government is vested in a board of commissioners of five members, elected annually. Pop. (1890) 4,145; (1900) 5,428.

JOHN H. COOK,
Editor 'Red Bank Register.'

Red Bat, a small reddish bat (*Lasiurus borealis*) common in the Eastern United States. See BAT.

Red-bellied Hawk. See RED-SHOULDERED HAWK.

Red-bellied Snake, a harmless snake (*Storeria occipitomaculata*) of the Eastern United States, whose belly is salmon red. It is dull brown above, with a paler stripe along the spine, bordered by one or more rows of blackish dots; a constant feature is three pale reddish blotches on the occiput. Its size and habits are similar to those of the garter-snakes. Two or three other species in the West have red bellies, and are sometimes locally known by the same name.

Red Book, an English government book containing the names of all persons in the service of the state.

Red-breasted, or **Robin, Snipe**, a dowitcher (q.v.).

Red Bug, or **Cotton-stainer**. See **COTTON INSECTS**.

Red Cedar. See **CEDAR**.

Red Cloud, Sioux Indian chief: b. about 1818. He first came into prominence as leader of the Indians in the Fetterman massacre near Fort Phil Kearny, Wyoming, in December 1866. In this event 100 men under Capt. Fetterman and Lieut. Brown, comprising the entire command, were slain. Red Cloud then became the acknowledged leader of the warrior Sioux, established a military dictatorship, and terrorized the region over which he ruled. In 1874 the Indians abandoned the North Platte country and went to the Red Cloud agency on the White Earth River, whence they continued under Red Cloud to make frequent raids. In 1880 he made a treaty of peace with the government which he faithfully observed.

Red Cloud, Neb., city, county-seat of Webster County, on the Republican River, and on the Chicago, Burlington & Quincy railroad; about 110 miles in direct line southwest of Lincoln. It is in an agricultural and stock-raising region. The chief manufacturing establishments are flour mills and machine shops. It has large lumber and stock yards and grain elevators. Its chief shipments are live-stock, wheat, corn, vegetables, and flour. The two State banks have a combined capital of \$40,000. Pop. (1890) 1,839; (1900) 1,554.

Red Cross Societies, a general name for those societies founded for assisting the wounded in time of war, so named because their distinctive badge is a red cross on a white ground. Such societies have been established in all civilized countries as a result of an international conference held at Geneva in 1863, which was followed next year by an international convention agreed upon at the same place, at which the International Treaty of Geneva was accepted and signed by a number of different nations. According to this all hospitals and hospital officials, and all in any way engaged in attending the sick and wounded in war, are treated as neutral parties. The society in England has four branches, two ambulance branches, one volunteer nursing branch, and one branch to raise funds and supplies, and societies in other countries. There is an international committee at Geneva which serves as a centre of communication between the different Red Cross societies throughout the world. In connection with this may be mentioned the decoration of the Royal Red Cross instituted by Queen Victoria in 1883, as a reward for women who have exerted themselves in aid of sick and wounded soldiers and sailors in time of war. The enameled crimson-and-gold cross bears the words "Faith, Hope and Charity," with the effigy of her majesty, the royal and imperial cipher, etc., and is attached to a blue ribbon and worn on the left shoulder.

The first war to bring the Red Cross service into activity was that of 1866 in Germany, Austria, and Italy. Austria had not yet joined the compact, but her citizens raised and gave to the service almost \$500,000. Germany's societies

supplied over \$3,000,000, and 500 volunteers, men and women, entered the service. The Red Cross work during the war proved the incalculable value of the organization. The next call on the service was the Franco-Prussian war. In Germany, more than 2,000 committees were formed at the beginning of the conflict, with a central committee at Berlin. More than \$14,000,000 was raised and used. France had less resource in readiness, but she raised and used nearly \$2,000,000, and her service cared for more than 100,000 wounded men. The next demand on the Red Cross was in 1876-8, when Turkey, Servia, Montenegro, Greece, and Russia became embroiled. In the beginning of this period of its work, the Red Cross service was regarded with suspicion by the military, but was soon solicited to take control of its treaty-province. It raised almost \$17,000,000 and applied over \$13,000,000.

The Red Cross emblem found its first opposing force in Turkey. The Turkish soldiers regarded it as of religious significance, and so violent was their prejudice that a red crescent was substituted in order to secure speediest recognition and co-operation. In the Japanese army the Red Cross service has been wonderfully effective. In 1886, Japan entered into this international treaty, and the mikado became president of a Red Cross society in a civil capacity. In the Turko-Russian contest, in the Tunisian, the Tonkin, and the Madagascar wars, the Red Cross was notably active. In the Græco-Turkish campaigns its work and sacrifice were heroic.

National Red Cross.—This is an American body incorporated under the laws of the District of Columbia, 1 Oct. 1881, reincorporated 17 April 1893, and reincorporated by act of Congress, June 1900; for the relief of suffering by war, pestilence, famine, flood, fires, and other calamities of sufficient magnitude to be deemed national in extent. The organization acts under the Geneva Treaty. The United States gave its adhesion by act of Congress 1 March 1882; ratified by the Congress of Berne 9 June 1882; proclaimed by President Arthur 26 July 1882; headquarters, Washington, D. C. The introduction and development of the Red Cross movement in the United States were chiefly due to Miss Clara Barton, the founder of the American branch. Previous to the organization of this branch there were many members of the Red Cross Society in the United States with Miss Barton as their representative. When the national branch was regularly formed Miss Barton was chosen leader. In the United States no laws have been passed to regulate Red Cross work. The national branch has no sub-societies or sub-committees; but patriotic and sympathetic men and women as individuals, or united in societies, are at liberty to assist and to co-operate with the Red Cross in raising money and in providing nurses and whatever the service requires. Whenever needed, this co-operation is active in every State and in most of the Territories.

The American National Red Cross did relief work in the Russian famine of 1892, and in Armenia in 1896.

The Red Cross work in Cuba during the war, as measured by service and contributions, was phenomenal. The total value of gifts, including cash donations, reached nearly \$4,000,-

RED DEER

000. When peace was declared, there yet remained starvation, sickness, disease, destitution, and desolation on the island. The Red Cross continued indefatigable in its work. In all its Cuban undertakings volunteer assistance and contributions of supplies were received from France, England, Belgium, Holland, Switzerland, Germany, Italy, Denmark, and Mexico. Almost all the Red Cross work during the war with Spain was done by temporary Red Cross auxiliaries, and other aid societies which went out of existence at the end of the war, and which had little or no connection with the National Society beyond that implied by the name.

National Support.—The governments of the United States, Great Britain, Germany, and Italy give no regular financial support to the Red Cross societies. In 1882 Congress appropriated \$1,000 for printing Red Cross literature; and since then, from time to time, has appropriated various sums for special purposes, but otherwise the society has received no financial support from the government of the United States. In Germany the government grants the society permission to hold occasional lotteries to secure funds. France allows an indemnity of 20 cents a day for each sick or wounded soldier cared for by the society in time of war. The Netherlands government pays the salary of the secretary, provides office quarters, allows \$400 a year for office expenses, pays the traveling expenses of an officer whose duties in connection with the work of the society may necessitate his leaving his home. Belgium gives financial support in time of war. Denmark contributes annually \$1,000. Austria gives \$2,400 annually for assistance in case of epidemics or great calamities. Switzerland appropriates \$5,000 annually for a special purpose. The emperor and empress of Japan give annually \$1,250. Russia pays for men taken care of by the society in time of war, at a rate agreed upon with the minister of war. In 1900 the emperor sanctioned a tax of 2½ cents on certain railroad tickets and \$2.50 on passports, such extra tax to be for the benefit of the Red Cross Society. The membership of the society is as follows: In 1903, in the United States, 298 members of the National Society; France, 55,000; Austria, 52,209; Hungary, 42,041; Japan, 804,814; Germany, main branch and affiliated societies, 300,000. In several other countries the society is well organized, with a large number of physicians, nurses, and general equipment.

Red Deer, or Stag, the common deer (*Cervus elephas*) of Europe and western Asia, which is typical of the family, and the ordinary "deer" of literature and poetry as well as of the chase. It much resembles the American wapiti, but is smaller and rather darker in general color. A fine specimen will stand four feet tall at the fore-shoulder and will weigh

about 300 pounds, but exceptional ones have weighed much more. Even larger are those of the Asiatic border and Asia Minor. The antlers of Scotch and Irish stags rarely exceed 33 inches in length; but those of eastern Europe and Siberia are far longer. Several different names have been given to the related deer of northern Asia, but they seem to be essentially the same as those of Europe, where they survive sparsely and under legal protection in almost all the countries. In the British Islands the wild red deer remains only in the Highlands of Scotland, but is "preserved" on many large estates and protected moors in both England and Ireland. The species is supposed to have been originally introduced into England from France, where it became very numerous, but since the 17th century it has been killed off in most parts of that kingdom to make way for the fallow deer, the venison of which is far superior, and the animal itself of a more manageable and placid disposition.

The stag has a fine eye, an acute sense of smell, and a good ear. When listening, he raises his head and erects his ears. When going into a coppice or other half-covered place, he stops to look round him on all sides, and scents the wind, to discover if any object be near that might disturb him. Though a simple, he is a curious and crafty animal. When hissed or called to from a distance, he stops short, and looks steadfastly, and, with a kind of admiration, at horses or men; and if the latter have neither arms nor dogs he moves on without betraying any symptoms of alarm. He eats slowly; and after his stomach is full, he lies down and ruminates at leisure.

In winter and spring this animal rarely ever drinks, the dews and tender herbage being sufficient to satisfy his thirst; but during the parching heats of summer, he not only frequents the brooks and springs, but searches for deep water wherein to bathe and refresh himself. He swims with great ease and strength, particularly when he is in good condition, his fat contributing to his buoyancy. His voice is stronger, louder, and more tremulous in proportion as he advances in age; and during the rutting season it is really fearful. The cry of the hind, or female, is not so loud as that of the male. The pairing season is in August; the time of gestation is between eight and nine months; and she seldom produces more than one at a time. The usual season of parturition is about May, and at that season the hinds are very cunning in concealing and tending, and exceedingly courageous in defending their young, which are exposed to many enemies. The "calf" (as the fawn is called by gamekeepers) never quits the dam during the whole summer; and in winter, the hind, together with all the males under a year old, assemble in herds, which are more or less numerous in proportion to the mildness or severity of the season. At the approach of spring they separate, none but those of the age of one year remaining associated. Stag-hunting, as carried on in the Highlands, is a sport capable of rousing all the manly ardor and energy of youth and manhood. The beauty, graceful and magnificent bearing of the animal, his sagacity in evading the stratagems of the hunter, or deer stalker, and his courage when at bay, add greatly to the pleasure of the chase. When the stag stands at bay, his effort is to do so in a river or lake, where

he has a great advantage over the dogs, for he firmly stands and holds his position, whilst they swim powerless around him. On land, even, a stag at bay has great advantage over the hounds, who exhaust themselves with their clamor, while he is in a comparative state of rest, and recovers his wind. In stalking deer, the animal is generally shot; but if he is only wounded, and has power to fly, then the dogs are slipped to the pursuit. But, in olden times, the chief reliance for pulling and killing the deer was in the dogs; and the fleetness and courage of their hounds were the pride of nobles and kings.

At the present day another sort of stag hunting takes place near Windsor Castle, and in some other parts of England. In this sport, which is contemptuously regarded by many persons, a captive stag is carried in a covered cart to the place where the chase is to occur, and then turned loose. After a brief interval, called giving the deer "law," a pack of hounds is sent upon his trail, and if the stag has spirit enough to run, the hunters following on horseback have a lively chase across the country, at the end of which the deer is retaken, unharmed if possible, and saved to run another day. This is a rather tame tradition of the ancient sport.

From the most remote periods, the stag has been the favorite object of the chase; and the severe forest laws of the earlier Norman monarchs sufficiently attest the importance which they attached to the sport. The afforesting of vast tracts of country, by which not only single cottages were destroyed, but whole villages swept away, and churches desecrated and demolished, was the fertile source of misery to the poorer inhabitants, and of injustice to the ancient proprietors of the soil; and the cruel inflictions of the oppressive laws which were enacted to preserve the deer, increased tenfold the curse arising from this tyrannical passion for the chase,—for it was a crime less severely penal to kill a man than to destroy or take a deer.

The ancient customs and laws of 'Venerie,' that science which our simple ancestors looked upon as one of the first accomplishments of the high-bred noble, and a knowledge of which was essential to his education, were formal and technical to an extreme degree. A few of the terms, betokening the different ages of the stag and hind, are still retained, though somewhat altered. The young of either sex is called a "calf"; after a few months the male becomes distinguished by the growth of the bossets, or frontal protuberances, on which the horns are afterward developed, which during the first year are merely rounded knobs, whence he takes the name "knobber." In the second year they are longer and pointed, and are called dags, and the animal has now the name of "brocket." In the third year, the first, or brow antler, has made its appearance, and the deer becomes a "spayad." In the fourth, the bezantler is added, and he is then termed a "stag-gard." He is a "stag" in the fifth year, when the third antler, or royal, appears; and in the sixth, the commencement of the sur-royal, or crown, is formed; when he takes the name of "hart," which name he retains through life. At this time he is called a "stag of ten," probably because the branches, including the sur-
